A large proportion of the presently available antifungal agents are claimed to derive their activity from interaction with the biosynthesis of ergosterol, the key sterol in most pathogenic fungi. An important target for the allylamines, naftifine and terbinafine, is the squalene epoxidase. Interaction with the epoxidation step results in a decreased availability of ergosterol and an accumulation of squalene. Although the squalene epoxidase is clearly the primary target for this class of antifungals, it still remains an open question whether the fungistatic or fungicidal effects originate from a decrease in ergosterol or squalene accumulation. Indeed, preliminary evidence suggests that squalene does not change the physicochemical properties of membranes. Much more is known about the primary and secondary effects of the azole antifungals, such as miconazole, ketoconazole, terconazole, and itraconazole. Most of the imidazole and triazole derivatives are highly potent and selective inhibitors of the cytochrome P-450–dependent 14α-demethylation of lanosterol (P-450_{14DM}). Their potency and selectivity are determined by the nitrogen heterocycle and to a much greater extent by the hydrophobic *N*-1 substituent. The triazole antifungals, terconazole and itraconazole, combine a high affinity for *Candida* P-450_{14DM} with an exceptionally low effect on mammalian cytochrome P-450. (AM J OBSTET GYNECOL 1991;165:1193-9.)

Key words: Squalene epoxidase, 14α -demethylase, cytochrome P-450, azoles, allylamines, morpholines

Mode of action studies on antifungals show how these agents interfere with a target in the fungus and highlight the differences between fungi and the mammalian host. Thus these studies may improve our knowledge of the biochemical systems in both parasite and patient. Furthermore, these chemical compounds can be used as tools to investigate the biochemical peculiarities of fungi.

Ergosterol is the most common sterol in *Candida* species and most pathogenic fungi where it plays a major architectural and functional role. Therefore it is not surprising that the ergosterol synthesis pathway has been recognized as a major target of antifungal agents. Indeed, most of the presently available antifungals are claimed to interfere with enzyme systems involved in the synthesis of this 24-alkylated sterol. For example, the allylamines inhibit the squalene epoxidase, the azole antifungals, the cytochrome P-450—dependent 14α -demethylase, and the morpholines interfere with the Δ^{14} -reductase and Δ^{8-7} -isomerase (Fig. 1).

It is the aim of this overview to discuss the molecular basis of anticandidal action of the squalene epoxidase and 14α -demethylase inhibitors.

The allylamines, naftifine and terbinafine, and the thiocarbamates, tolciclate and tolnaftate, induce an accumulation of squalene and a concomitant decrease in ergosterol synthesis in fungal cells. This indicates that both the allylamines and thiocarbamates inhibit the squalene epoxidase (Fig. 1). In dermatophytes there is a clear correlation between the inhibition of this important enzyme of the ergosterol biosynthesis pathway and inhibition of growth. However, although the squalene epoxidases of Candida albicans and Candida parapsilosis are almost equisensitive to terbinafine (95% inhibition at terbinafine concentrations between 0.2 and $0.9 \,\mu \text{g/ml}$), the latter species is much more susceptible to growth inhibition. Furthermore, the epoxidase of Candida glabrata is, compared with that of C. parapsilosis, about three times less sensitive to this allylamine, whereas the minimum inhibitory concentration value is 250 times higher. 1 It should be noted that penetration problems do not seem to explain these differences, because activity against squalene epoxidase in intact cells and crude extracts of Candida cells is similar.2 However, poor penetration of the Candida cell membrane accounts for the lack of activity of the thiocarbamates against yeasts.3

Squalene epoxidase inhibitors

Ryder¹ speculates that fungal species differ in their sensitivity to a decreased availability of ergosterol and also in their reaction to the intracellular accumulation of squalene. Indeed, the filamentous form of *C. albicans*

Fig. 1. Reaction sequences involved in the synthesis of ergosterol and target sites for allylamines, thiocarbamates, azole antifungals, and morpholines.

is more susceptible than the yeast form, whereas ergosterol biosynthesis is almost equally affected in both forms. Filamentous fungi seem particularly susceptible to the allylamines and require only partial ergosterol biosynthesis inhibition for full inhibition of growth. Does the sensitivity to the accumulating squalene determine the susceptibility? *Candida* species can grow semianaerobically. Under this condition low amounts of ergosterol are formed and high levels of squalene are found.² Thus *Candida* seems to be able to tolerate high amounts of squalene. It has been speculated that filamentous fungi are more susceptible to squalene accumulation. However, of interest is the high radioactivity incorporated from carbon 14 acetate into squa-

lene by *Trichophyton mentagrophytes* grown under control conditions.⁴ Almost 24% of the total radioactivity measured in the lipid extracts is found in the squalene fraction; this is only two times less than the radioactivity incorporated into ergosterol.⁴ The presence of squalene did not prevent growth.⁴ This is not surprising because microgram amounts of squalene have been found in *Phytophothora cactorum*, a fungus unable to epoxidise and cyclisize squalene to lanosterol,^{5, 6} and Margalith⁷ hypothesized that in *Phytophothora* "squalene itself may be assuming the architectural role (bulk function?) of sterols, allowing vegetative growth." Differential scanning calorimetry of multilamellar vesicles of dipalmitoylphosphatidylcholine containing increasing

concentrations of squalene (10 to 35 mol %) has shown that squalene, even at 35 mol %, induced no significant change (<1° C) of the dipalmitoylphosphatidylcholine midtransition temperature or the enthalpy of melting (unpublished results). This suggests that squalene does not change the physicochemical properties of the membranes and thus differs from its cyclic products formed by the squalene cyclase, such as lanosterol (Fig. 1). Indeed, the addition of lanosterol (5 to 15 mol %) to dipalmitoylphosphatidylcholine multilamellar vesicles lowered the transition temperature slightly but had a major effect on the enthalpy of melting,8 suggesting that lanosterol interacts with the phospholipids present. Therefore it is still an open question whether growth inhibition and especially fungicidal activity are consequences of the decreased availability of ergosterol, squalene accumulation, or both. Thus although the squalene epoxidase is clearly a target for the allylamines, more studies are needed to clarify the molecular basis for their fungistatic and fungicidal activity.

14α-Demethylase inhibitors

Since the synthesis of miconazole and clotrimazole in the 1960s, a huge number of azole derivatives have become available. Some are used topically, whereas others are used both topically and orally. All belong to the class of 14\alpha-demethylase inhibitors. 9, 10 Their antifungal activity originates from binding to a cytochrome P-450 (P-450_{14DM}) involved in the 14α -demethylation of lanosterol (in Saccharomyces cerevisiae, C. glabrata, and mammalian cells) or 24-methylenedihydrolanosterol (in filamentous fungi, the yeast form of Histoplasma capsulatum, Cryptococcus neoformans, and a number of C. albicans isolates) (Fig. 1). It should be noted that contrary to C. albicans, C. glabrata uses lanosterol preferentially as substrate.

Before a discussion of the interaction of the azole antifungals with this key enzyme of sterol biosynthesis, we should look at cytochromes P-450, which are present in just about every phyla in which they have been sought. They are membrane bound (mitochondrial inner membrane and endoplasmic reticulum) in eukaryotes, whereas the prokaryote forms are soluble proteins. Cytochrome P-450s catalyze the synthesis or metabolism of a long list of key compounds. Examples are sterols (e.g., ergosterol and cholesterol), steroids (e.g., androgens and estrogens), bile acids, vitamin A, thromboxane A2, prostacyclin, and leukotrienes.11 They also play an important role in the activation of vitamin D and the metabolism of xenobiotics. Most of the cytochrome P-450s are classified as monooxygenases. This means that they catalyze the following reaction: $NADPH_2 + O_2 + RH \Rightarrow NADP^+ + H_2O + ROH$. In this reaction, RH represents a substrate (e.g., lanosterol) to be oxidized by the P-450 enzyme. The reaction

requires molecular oxygen of which one oxygen atom is inserted into the substrate, whereas the other oxygen atom is reduced to water. NADPH2 provides the electrons needed for the activation of this process. The active site of P-450 contains a ferric prosthetic heme group, the substrate binds to the protein moiety of the P-450, and the heme iron is reduced. Molecular oxygen is bound, reduced, and activated at this site (Fig. 2, A

The specific enzymatic function of the cytochrome P-450s, that is, to activate oxygen for insertion into a substrate, originates from the electronic structure of the heme iron linked to the thiol of a cysteyl residue of the P-450 protein moiety (Fig. 2, A). The typical absorption maximum at 450 nm of the reduced carbon monoxide-P-450 complex also originates from the specific interaction of the prosthetic group with the protein. The name of this hemoprotein originates from this property. Indeed, the name cytochrome P-450 describes a carbon-monoxide-binding pigment, which absorbs at about 450 nm.

As shown in Fig. 2, B, azole antifungals bind to the heme iron and compete in this way with oxygen binding and activation. This results in inhibition of the P-450catalyzed reaction. Because carbon monoxide also competes with oxygen for the same binding place, we can measure the interaction of an azole antifungal by adding it to a cytochrome P-450-containing microsomal or mitochondrial fraction, reducing the heme iron (with dithionite), and bubbling the suspension with carbon monoxide. Binding of the inhibitor to the heme iron will reduce absorption at 450 nm, and this decrease is a measure for the amount of inhibitor bound. For example, 50% inhibition of carbon monoxide binding to microsomal P-450 from C. albicans is obtained with nanomolar concentrations of the imidazole derivatives, miconazole and ketoconazole, and the triazoles, terconazole and itraconazole (Table I). Another triazole derivative, fluconazole, is a much less potent inhibitor of carbon monoxide binding, indicating that it has a lower affinity for the Candida P-450. This already indicates that the potency of an azole derivative is determined not only by its binding to the heme iron. It has been shown previously that the activity is determined, at least partly, by the hydrophobicity of the N-1 substituent (Fig. 2, B).12 For example, itraconazole and its imidazole analog form equistable complexes with C. albicans P-450; the less hydrophobic ketoconazole forms a less stable P-450 complex, and the stability of the complex is not increased by replacing the imidazole by a triazole (R42164).12

Comparing the amino-acid sequences of mammalian P-450(s) (e.g., those involved in steroid synthesis and metabolism) with that of C. albicans P-450_{14DM} shows less than 25% identical amino acids.13 Therefore it should

Fig. 2. A, Sketch of part of cytochrome P-450_{HDM}. Iron protoporphyrin and substrate (lanosterol) bound to a hydrophobic domain of the polypeptide chain are shown. The iron (Fe²⁺) is linked to the thiology a cysteyl residue (C) that is part of a conserved region of the polypeptide in C. albicans P-450_{HDM} H, Histidine; R, arginine; I, isoleucine; G, glycine. Molecular oxygen is attached to the ferrous heme iron. B, Sketch of azole (terconazole)–P-450 complex. Triazole ring is linked to the sixth position of the ferric (Fe³⁺) heme iron by way of N-3. N-1 substituent is bound to a hydrophobic binding site in P-450.

be possible to synthesize selective anti-Candida compounds. The selectivity of the azole antifungals may be determined by both the azole and the N-1 substituent of the molecule. Terconazole and itraconazole (triazole derivatives) are, as shown in Fig. 3, more selective affectors of the yeast P-450s than the imidazole antifungals miconazole, clotrimazole, and bifonazole. However, major differences in selectivity are found antifungals.

the topically active imidazole antifungals.^{10, 13} For example, clotrimazole and miconazole interact preferentially with the *Candida* P-450, whereas bifonazole has highest affinity for P-450(s) of the testicular microsomes from piglets (Fig. 3). Replacing the imidazole ring of ketoconazole with a triazole ring (R42164) slightly decreases the interaction with the microsomal P-450(s) from piglet testes.¹³ Fifty percent inhibition is

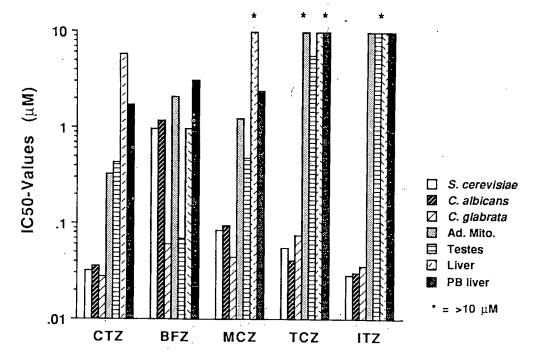

Fig. 3. Effects of clotrimazole (CTZ), bifonazole (BFZ), miconazole (MCZ), terconazole (TCZ), and itraconazole (ITZ) on microsomal P-450s from Saccharomyces cerevisiae (S. cerevisiae), C. albicans, C. glabrata, piglet testes, and liver from untreated and phenobarbital (PB) pretreated rabbits, and on mitochondrial P-450 from bovine adrenal glands (ad. mito). IC_{50} values = drug concentrations needed to inhibit carbon monoxide binding the heme iron by 50%. P-450 content = 0.1 nmol·ml⁻¹. Methods used are described in ref. 20.

Table I. Effects of azole antifungals on carbon monoxide-binding to microsomal P-450 and on ergosterol synthesis

	IC_{50} values (nmol/L)				
	P-450*		Ergosterol synthesis†

Itraconazole	30.1	35.6	80.3	40.5	
Fluconazole	248.0	260.0	6530.0	1790.0	

IC₅₀ values = concentrations needed to achieve 50% decrease in ΔA (448 nm - 490 nm).

†Cells were first grown for 16 hours (8 hours in an orbital shaker) at 30° C in a polypeptone: yeast extract: glucose (10:10:40 & gmL/L) medium and then washed and resuspended in a 0.1 nmol/L potassium phosphate buffer containing 56 nmol/L glucose (pH 6.5). [4C]-Acetate, azole antifungals, and/or dimethylsulfoxide were added, and the cell suspensions were incubated for 2 hours at 30° C in an orbital shaker (300 rpm). At the end of the incubation period, sterols were extracted and separated by thinlayer chromatography. IC₅₀ values: Concentrations needed to obtain 50% inhibition of [14C]-incorporation into ergosterol.

achieved at 0.39 µmol/L (ketoconazole) and 0.49 µmol/L (R42164). Replacing the triazole of itraconazole with an imidazole ring slightly increased the effects on adrenal mitochondrial P-450 (from 0% to 25% inhibition at 1 μmol/L) but did not enhance the effects on testicular microsomal P-450.18 Furthermore, comparing the effects of ketoconazole with those of norketoconazole (deacylated ketoconazole) indicates that minor structural changes in the nonligand part (the N-1 substituent) affects the interaction with P-450. Norketoconazole has two- and three-times lower affinity for the microsomal P-450 from piglet testis and C. albicans, respectively. These results suggest that the nonligand hydrophobic part of the azoles has a greater impact on

^{*}Membranes used were isolated from C. albicans (ATCC 28516, microsomes) and C. glabrata (B 16205, microsomes).

Fig. 4. Effects of terconazole on ergosterol synthesis in C. albicans grown for 16 hours in casein hydrolysate, yeast extract, glucose medium supplemented with ¹⁴C-acetate and terconazole and/or dimethylsulfoxide. Homogenization of the cells, saponification, extraction, and separation of the sterols by high-performance liquid chromatography was described previously. [14C]-Acetate and drug (1 µmol/L) and/or solvent were added at inoculation. 0 = the control. Under the conditions used, an IC50 value of 45.9 nmol/L was found.

the selective interaction with P-450 enzymes than does the azole moiety and also prove that it is possible to synthesize highly potent and selective P-450 inhibitors.

The major P-450 present in C. albicans microsomes is involved in the 14α -demethylation of lanosterol or 24-methylenedihydrolanosterol, that is, P-450_{14DM}. Thus the effects of azole antifungals are suggestive of an interaction with the 14α-demethylase and thus with ergosterol synthesis. Inhibition of ergosterol biosynthesis has been shown with miconazole, terconazole, ketoconazole, itraconazole, and/or saperconazole in C. albicans, C. glabrata, Candida lusitaniae, Pityrosporum ovale, T. mentagrophytes, Paracoccidioides brasiliensis, Histoplasma capsulatum, and/or Aspergillus fumigatus.4, 8-10, 13, 14 The results listed in Table I show that after 2 hours of contact of C. albicans and C. glabrata with miconazole, ketoconazole, terconazole, or itraconazole, 50% inhibition of ergosterol synthesis from [14C]acetate is already reached at concentrations < 0.1 µmol/L. As could be expected from its lower effect on carbon monoxide binding to the microsomal C. glabrata and C. albicans P-450s, a much higher concentration of fluconazole is needed to reach 50% inhibition of ergosterol synthesis. Similar results are obtained after longer incubation periods.10 For example, complete ergosterol depletion is achieved when C. albicans is incubated for 24 hours with 0.1 µmol/L of itraconazole and ketoconazole, whereas 100% inhibition of ergosterol synthesis is not reached with 100 µmol/L fluconazole.10 It should be noted that ergosterol depletion is a prerequisite to block-cell proliferation.15

Inhibition of ergosterol synthesis coincides with the accumulation of 14-methylated sterols (Fig. 4). This proves that indeed the inhibition of ergosterol synthesis originates from interaction with the P-450-dependent 14α -demethylase. In the presence of terconazole, most of the radioactivity derived from [14C]-acetate is found in 14α -methyl-ergosta-8,24(28)-dien-3 β ,6 α -diol (3,6diol). The 6-hydroxylation may be part of the Δ^{5,6} double-bond insertion, one of the last reactions in ergosterol synthesis. The accumulation of this 3,6-diol in azole-antifungal-treated Candida may originate from the inability of the $\Delta^{5.6}$ -desaturase to use 14-methylsterols as substrates. Studies by Watson et al. 16,17 suggest that azole-induced growth inhibition originates in yeast from inhibition of the 14α-demethylase and the consequent accumulation of this 3,6-diol. Conclusive evidence has been collected showing that the 14-methylated sterols induce permeability changes, membrane leakiness, changes in membrane-bound enzymes, inhibition of growth, and cell death.8,9,18 For example, one of the most striking changes is an uncoordinated synthesis of chitin. Patches of chitin are found over the cell wall instead of being localized at the septa and growth tip. 14, 18 The accumulation of chitin disturbs the normal sequence of cell separation, resulting in chains and clusters of interconnected cells and causing abnormal swelling and bursting of cells.18 Other membrane-bound enzymes are also affected. The reduced nicotinamide adenine dinucleotide-dependent fatty acid desaturase requires the presence of a microsomal electron transport system that consists of reduced nicotinamide adenine dinucleotide cytochrome b5 reductase and cytochrome b5. All three components of the system are embedded in the microsomal membranes and affected by the fluidity of the membrane.19 It has been proven that the fatty acid desaturase of C. albicans is partially inhibited by the azole-induced (e.g., miconazole and ketoconazole) inhibition of ergosterol synthesis and the consequent decreased availability of ergosterol and/or accumulation of 14α-methylsterols.¹⁸ An inhibition of the fatty acid desaturase results in much higher levels of saturated fatty acids (e.g., palmitate) and thus in an increased membrane rigidity.20 This further contributes to the antifungal activity of azole antifungals.

The in vitro activity of terconazole against yeasts: Its topical long-acting therapeutic efficacy in experimental vaginal candidiasis in rats

Jan Van Cutsem, PhD

Beerse, Belgium

The activity of the broad-spectrum triazole antifungal terconazole was evaluated in vitro by the serial decimal dilution technique in broth media. The best correlation between in vitro and in vivo activity was found in brain-heart infusion broth and Eagle's minimum essential medium. All strains of *Candida albicans*, *C. tropicalis*, *C. krusei*, *C. parapsilosis*, *C. guilliermondii*, *C. glabrata*, and *Trichosporon beigelii* tested were susceptible. Terconazole blocked the morphogenetic transformation from the yeast into the filamentous form at concentrations of 0.008 to 0.05 µg/ml. In experimental candidiasis in castrated rats with estrogen-induced permanent pseudoestrus, topical treatment with terconazole was superior to miconazole, clotrimazole, econazole, butoconazole, tioconazole, sulconazole, bifonazole, valconazole, fenticonazole, nystatin, and amphotericin B in the various schedules used. A 3-day once-daily intravaginal application of terconazole 0.8% was usually sufficient to provide a functional therapeutic period of 7 days because of prolonged high biologically active antifungal levels in the vagina. No side effects were observed at any concentration of terconazole. (Am J Obstet Gynecol 1991;165:1200-6.)

Key words: Terconazole, anti-Candida activity in vitro, experimental vaginal candidiasis in rats, reference drugs, topical treatment, high antifungal levels in the vagina 4 days after therapy

During the past three decades, two major changes have occurred in the epidemiology of vaginal Candida infection: there has been a large increase in the incidence of the disease, and the percentage of non—Candida albicans infections has increased, especially C. (Torulopsis) glabrata.¹

With the introduction of nystatin in the 1950s, progress was made in topical therapy, but a more important step in the management of vulvovaginal candidiasis was the synthesis of the topical broad-spectrum imidazoles miconazole, econazole, isoconazole, and clotrimazole. Short-term oral medication became available with the introduction of ketoconazole, itraconazole, and fluconazole. However, topical treatment of this infection is still widely used, because safe and efficacious drugs for short-term treatment are available. This article deals with the in vitro activity of terconazole against yeasts responsible for vaginal mycosis. Its in vivo topical efficacy in experimental vaginal Candida infection in rats will be compared with that of other topical drugs.

Fig. 1. Chemical structure of terconazole.

Material and methods

Terconazole (R42 470) is a broad-spectrum topical antifungal triazole derivative with a molecular weight of 532.47 (Fig. 1).²

In vitro experiments. The activity of terconazole was evaluated in broth media with serial decimal drug dilutions³ ranging from 100 to 0.01 µg/ml and drugfree controls. The sensitivity of several strains of

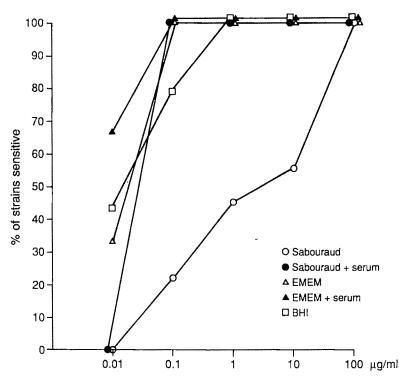

Fig. 2. Sensitivity of *C. albicans* to terconazole in broth media. Percentage of strains sensitive at stated concentrations.

C. albicans to terconazole was tested in tubes containing 5 ml of Sabouraud (n = 52), Sabouraud supplemented with 10% inactivated bovine serum (n = 3), Eagle's minimum essential medium (EMEM) supplemented (n = 3) or not (n = 3) with serum, and brain-heart infusion broth (BHI) (n = 28) (Fig. 2). BHI was used for strains of C. tropicalis (n = 26), C. krusei (n = 3), C. parapsilosis (n = 6), C. guilliermondii (n = 6), C. glabrata (n = 6), and Trichosporon beigelii (n = 6) (Fig. 3). The final concentration in the test media consisted of 2 to 4 × 10⁴ colony-forming units (CFU) per ml. The cultures were incubated for 2 weeks at 25° C and observed regularly. Final observations were made at the end of this period. The strains were considered sensitive if at least 90% of growth was reduced in the treated cultures versus the control cultures. To study the blocking of the morphogenetic transformation from the yeast into the filamentous form, four strains of C. albicans and one C. parapsilosis strain were tested with terconazole, miconazole, clotrimazole, and sulconazole (Table I). This experiment was performed in EMEM supplemented with nonessential amino acids and 10% fetal calf serum. The inoculum consisted of 150 CFU/ml. The drugs were diluted by fourfold serial dilutions at concentrations from 5 to 0.00064 µg/ml. The tests were performed at 37% C in a humidified atmosphere containing 5% CO₂. Cultures were observed for 7 days,^{4,5} and the presence or absence of hyphae was determined microscopically.

In vivo experiments. Female Wistar rats of 100 gm underwent ovariectomy and hysterectomy. After recovery, permanent pseudoestrus was induced by weekly subcutaneous injection of estradiol undecylate (1 ml of oily solution at 0.1 mg/ml). The rats were infected intravaginally with $8 \times 10^5 \text{ CFU}$ of *C. albicans*. They were treated topically twice daily for 3 days, starting 24 hours after infection with a volume of 0.2 ml of various concentrations of terconazole, miconazole, clotrimazole, econazole, nystatin, or amphotericin B (Table II). In other animals treatment with terconazole, miconazole, clotrimazole, butoconazole, tioconazole, sulconazole, bifonazole, valconazole, and fenticonazole was started 3 days after infection (Table III) and was administered twice daily over a 3-day period.

Rats with vaginal candidiasis were also treated with various azoles once daily, starting 3 days after infection for 3 consecutive days; some animals received one-shot therapy (Table IV). In all experiments excipient-treated animals (polyethylene glycol 200) were included. The evaluation was based on cultures in Petri plates from vaginal smears on Sabouraud agar supplemented with antibacterial antibiotics, on BiGGY agar, and on subcultures on agar media of vaginal swabs in Sabouraud broth tubes. The infection was checked 7

days after the last drug application. Animals were considered cured if all culture results were negative, and markedly improved if fewer than 25 colonies of *C. albicans* were present on the Petri dishes or if the subculture results from the swabs in the broth medium were positive. All others were considered treatment failures.

Bioassay study. The biologic antifungal level of terconazole was determined in the vaginas of rats after topical treatment once daily for 3 consecutive days with terconazole 0.8% in polyethylene glycol 200 or with the excipient (Fig. 4). Two groups of rats were used: (1) castrated animals in permanent pseudoestrus, which received weekly injections of estrogens and were infected with *C. albicans*, and (2) nonestrogenized, ovulating, noninfected rats.

Eight hours, 24 hours, and 4 days after completion of the treatment, six rats treated with the excipient or the drug were killed in both groups. The vagina and the uterus were removed and immediately deep frozen. For the bioassay experiment, the base layer of EMEM containing 2% of bacto agar was poured into Petri dishes of 140 mm diameter. Ten milliliters of seed layer, EMEM containing 0.75% of bacto agar, and 4×10^5

CFU of C. albicans ATCC 28 516 per milliliter were poured uniformly over the base layer. Blank disks with a half-inch diameter were placed on the plates and dosed with various concentrations of terconazole in a volume of 0.05 ml. The vagina and the uterus were removed together, frozen, and then cut transversely, and the inner part was touched briefly onto the medium in one location and then placed on the surface in another. The test plates were left for 24 hours at 4° C to allow for prediffusion of drugs and then incubated for 48 hours at 25° C. The inhibition zones were measured, and the zone diameters were used to calculate terconazole concentrations in micrograms per milliliter or per gram value (Fig. 5).

Results

In vitro experiments. Terconazole proved to be highly active against C. albicans strains in vitro. The sensitivity of C. albicans to terconazole was more pronouced in long-term experiments in richer media compared with the classic Sabouraud broth (Fig. 2). In Sabouraud broth, the efficacy of the drug was rather poor, but in serum-supplemented medium, as well as in EMEM and BHI, drug efficacy was increased. The efficacy results with terconazole, obtained in BHI broth for C. tropicalis, C. krusei, C. parapsilosis, C. guilliermondii, C. glabrata, and Trichosporon beigelii, compared with those in Sabouraud broth, were in line with results for C. albicans (Fig. 3). Terconazole was able to block the morphogenetic trans-

cipient treatment had no influence on this condition. When topical therapy was begun 24 hours after infection and continued for only a short time (3 days twice a day), the first-generation, broad-spectrum imidazoles were active (Table II). However, nystatin was poorly active, and amphotericin B was not active at all. Of the imidazoles, miconazole was the most effective, but terconazole was far more potent.

When the onset of therapeutic treatment was delayed to day 3 after infection (Table III) and administered for 3 days twice daily, miconazole was the most efficacious of the imidazoles tested, followed by clotrimazole; the therapeutic results of the other imidazoles remained inferior. The therapeutic efficacy of terconazole was more pronounced at lower concentrations.

In therapeutic regimens, in which treatment started 3 days after infection and was administered either in a single shot or once daily for 3 consecutive days, terconazole was the most efficacious compound (Table IV). Side effects were observed in none of the terconazole-treated rats.

Bioassay. The antifungal levels in the vagina as measured by bioassay evaluation are presented in Fig. 4, and an example is shown in Fig. 5.

In both castrated, estrogenized, infected rats (group 1) and noncastrated, normally ovulating, estrogenized, infected rats (group 2), high levels of terconazole were detected after therapy. No inhibition was observed in the excipient-treated animals. Eight hours after the end of drug treatment, the levels per gram were 231 μg (SD 24) and 153 μg (SD 38) for groups 1 and 2, respectively. They decreased to 12 μg (SD 3.3) and 45 μg (SD 13) after 24 hours and to 8.7 μg (SD 2) and 7.4 μg (SD 1.4) after 4 days for groups 1 and 2, respectively. The concentration of terconazole present in the rat vagina 4 days after the last topical dosage was higher in all animals than the efficacy concentration of all yeast strains tested.

Comment

Terconazole is a potent broad-spectrum triazole. It is active against all yeast strains evaluted in vitro. In

Fig. 5. Bioassay in EMEM agar of vagina and uterus of rats treated with the excipient (upper left) and with terconazole 0.8%.

vitro results may be largely influenced by various factors.^{5,7} It has been established that the ingredients of the test medium play an important role in demonstrating the real potency of a drug. A good correlation between in vitro antifungal potency of terconazole and its in vivo efficacy was found by using BHI broth and EMEM. Both media support yeast development very well. BHI is a rich medium with a pH of 7.2 to 7.4, which allows higher concentrations of active nonprotonated drug. In EMEM supplemented with serum, the superiority of terconazole to other azoles tested was demonstrated by blocking the morphogenetic transformation of the yeast form into the filamentous form of *C. albicans* and *C. parapsilosis*.

Experimental vaginal candidiasis in ovariectomized and hysterectomized rats that were kept in permanent pseudoestrus by weekly administration of estrogens remained unchanged for at least 3 months. A small number of rats became spontaneously *Candida*-negative in a follow-up period of 8 months. In this model oral and topical therapy can be evaluated under the right conditions. Miconazole 2% must be administered twice daily for 5 days to obtain cure rates of 90%. For nystatin and amphotericin B, the treatment must be longer and

started very early (24 hours after infection) to eradicate the disease completely. The therapeutic efficacy of miconazole in the rat model has already been confirmed in the treatment of humans worldwide during the two decades of its use (first introduction of miconazole in human therapy was in 1971). Terconazole proves to be more active at lower concentrations. When the onset of treatment was delayed to 3 days after infection with a schedule of twice daily for 3 days, eradication of the disease was more difficult. Of all the reference substances, miconazole was the most potent, but a higher percentage of terconazole-treated rats was cured at lower concentrations. With the treatment schedule modified to once daily for 1 or 3 days, the superiority of terconazole over the reference substances was confirmed. At a concentration of 0.8% given once daily for 3 days or 4% given as a single shot starting 3 days after infection, 92% and 100% of the rats, respectively, were cured.

The high antifungal levels of 0.8% terconazole, administered once daily, in the vagina of infected, castrated, and noninfected, noncastrated rats that were still present 4 days after the end of therapy were usually higher than the inhibitory concentration needed for all

strains tested. This is especially important in view of the increasing number of non-albicans Candida infections. A short treatment schedule with terconazole 0.8% once daily for 3 days more or less covers a therapeutic period of 7 days for infections by the various yeast species, all causative agents of vaginal candidiasis. Cohen⁸ treated women with either 80 mg terconazole suppositories for 3 days or with 0.4% cream for 7 days once daily. The mean levels of terconazole in vaginal secretion 3 days after the end of treatment were 36 and 58 µg/ml, respectively. These concentrations were higher than those obtained in rats. The persistence of high levels of terconazole in the vagina is responsible for the complete eradication of the infection and for the reduction of risks for relapses. Such high concentrations of terconazole in the vagina allowed rapid elimination of yeast cells, subcellular changes in fungal cell membranes, complete necrosis of the fungi, and the absence of abnormalities in the vaginal epithelium as shown by scanning and transmission electron microscopy, confirming the safety of terconazole therapy in experimental animals.9, 10 Therefore the results obtained in the various experiments support the theory that terconazole is an excellent antifungal for topical therapy of human vaginal candidiasis in short schedules and has very low relapse rates.11-16

Vulvovaginitis: The role of patient compliance in treatment success*

Sam A. Nixon, MD

Houston, Texas

Vulvovaginitis caused by Candida organisms accounts for a large number of annual office visits to physicians, often for recurrent infection. Despite the availability of many effective antifungal preparations, treatment failures continue to occur because of poor compliance with therapy. Several factors may foster noncompliance. Those involving the patient include denial of illness, misconceptions regarding the nature of the infection or its treatment, a misunderstanding of symptomatic relief versus microbiologic cure, dislike of the dosage form, nonsupport of the sexual consort, or intolerance of side effects. The cost of treatment, inconvenient dosage form, and prolonged duration of therapy may also contribute to noncompliance. This article offers suggestions for optimizing compliance and successful treatment. Two perceived means to this end are improved patient education and the use of short-term therapy in convenient dosage form. (AM J OBSTET GYNECOL 1991;165:1207-9.)

Key words: Patient compliance, vaginal mycoses, vulvovaginitis

The increasing frequency of vulvovaginitis has been traced to a number of diverse factors, including the widespread use of oral contraceptive pills and antibiotic administration. Whatever the underlying reasons, no one regards vulvovaginitis as a trivial disorder, because a large number of office visits to gynecologists are for the treatment of its symptoms. Such an overwhelming caseload translates into enormous morbidity among women and an ongoing challenge to clinicians.

A significant proportion of office visits for vulvovaginitis represent repeat visits by patients with chronic or recurrent infections despite the availability of seemingly effective therapeutic agents. Thus the question naturally arises, "Why are there so many therapeutic failures?" Aside from host factors, the most likely answer is poor patient compliance, which can compromise even the most effective treatment regimen. Hence the real challenge to physicians may not lie in diagnosing this condition, but rather in effecting better patient compliance.

This article explores the factors contributing to poor drug compliance and some of the options available to physicians for overcoming these problems.

Therapeutic regimen and compliance

It is generally held that the more precisely a therapeutic agent meets the needs of a specific patient, the

From The University of Texas Health Science Center at Houston. Reprint requests: Sam A. Nixon, MD, Director, Division of Continuing Education, The University of Texas Health Science Center at Houston, 1100 Holcombe Blvd., Houston, TX 77030.

*Dr. Nixon's presentation was updated from a talk given previously and published in the Journal of Clinical Practice in Sexuality. 610133247

more likley he or she is to comply with the prescribed regimen. The main patient factors to consider in selecting a therapeutic treatment for vulvovaginitis are listed in Table I. When such factors as dosage form and regimen, occupational or personal requirements, or prior patient experience with adverse effects such as burning or itching are taken into consideration by the clinician, the chances of patient compliance increase. For example, some patients may prefer the consistency of vaginal creams to suppositories or be less capable of complying with a 7-day regimen than a shorter regimen because of personal or business constraints. Thus the choice of therapeutic regimen can have a dramatic effect on compliance.

In general, the ideal therapeutic agent for vulvovaginitis is regarded as one that would (1) permit single-dose administration, (2) act rapidly, (3) be free of side effects, (4) be safe for use during pregnancy, and (5) offer a high long-term rate of efficacy. 1, 2 Problems with patient compliance have spurred efforts by pharmaceutical companies to improve treatment courses along these lines.

Psychosocial factors and compliance

Failure to comply with a full treatment regimen and subsequent treatment failure may stem not only from a less than optimal therapeutic choice but from numerous psychosocial factors. These are often a result of negative social influences and lack of information.³ These factors can include denial of the problem because of embarrassment, mistaking symptomatic relief for a cure, and in some cases even failing to understand anatomy and the nature of the infection. Another reason can be deferral to the preferences of a sex partner,

Table I. Patient considerations in choosing an antifungal agent for vulvovaginitis

who may find intercourse during treatment objectionable.

The cost of treatment can also profoundly affect compliance. This is especially true if friends or pharmacists inform the patient of less expensive over-the-counter preparations that are available. Because such information may discourage or alienate an otherwise cooperative patient, it is important for physicians to discuss their therapeutic recommendation in light of the availability of over-the-counter drugs.

Overcoming noncompliance

The chances for long-lasting resolution of symptoms and a microbiologic cure can be improved if physicians take a systematic approach to patient communication and education regarding dosing, side effects, and safety. It is essential that physicians take into consideration factors that influence convenience for the individual patient (Table II), because choosing regimens that control symptoms without disrupting daily life are more likely to be followed. For example, once-daily administration at bedtime has the advantage of facilitating drug retention, avoiding leakage onto daytime clothing, and coinciding with other nighttime rituals that afford a reminder to self-medicate.

In addition, choosing a short therapeutic regimen can minimize the opportunities for noncompliance. However, troublesome side effects can undermine even the most brief regimens. Fortunately, only a small percentage (≤7%) of women using the imidazole antifungal cream preparations experience adverse reactions such as pruritus, burning, or irritation, which also characterize the infection itself.⁵ It is important that physicians apprise their patients of these limited effects.

Pregnant patients can be reassured about the safety of treatment during the second and third trimesters, because its use has not been associated with any adverse fetal effects. However, imidazole and triazole antifungal drugs are not recommended for use during the first trimester, because embryotoxicity has been reported in some laboratory animals.

Table II. Factors influencing convenience of therapy in cases of vulvovaginitis

Factor	Recommendation
Daily timing of dose	Bedtime dosing
Frequency of administration	Once-daily administration
Length of treatment course	Short term (1-3 days)
Dosage form	Topical/oral agents
Use with menses	Advised for rapid response*
Sexual intercourse	Preferably abstain during short-course therapy or use condoms
Relation to regular daily routines	Follow above for no disruption of daily life

Modified from Sobel J. In: Sobel J, ed. Clinical perspectives: terconazole, an advance in vulvovaginal candidiasis therapy. New York: BMI/McGraw Hill, 1988.

*If menses remain a major barrier to patient cooperation, physicians should allow treatment to be postponed rather than risk noncompliance.

Cooperative decision making

Involving the patient in decisions regarding drug choices can go a long way toward improving patient communication and ensuring patient compliance. What may seem like a perfectly reasonable therapeutic approach to the physician may cause difficulties for the patient, and unless such matters are discussed, compliance may suffer. Fortunately, many aspects of treatment lend themselves to mutual decision making.

A patient's acceptance of a dosage form, for example, is governed by ease of use and the physical properties of the drug. Product consistency, the volume of application, color, scent, and applicator size all bear on the acceptability of therapy. Where possible, patients should be offered a choice of formulations, if there is no trade-off in efficacy or treatment duration.

Although sexual transmission of *Candida* vulvovaginitis remains to be definitively shown, I believe that sexual abstinence should be encouraged because it avoids compromising treatment and eliminates potential reinfection. Because effective treatment can often be achieved with a single dose or a 3-day regimen, sexual abstinence is usually not a problem and can be discussed cooperatively with the patient.

Education and communication

Misconceptions about the nature of vulvovaginitis and its treatment may also contribute to poor compliance with therapy. Thus patients should be told that treatment should be continued during the menses because topical medications are formulated to adhere to the vaginal mucosa even during menstruation. Further, discussing the effect of the menses on the vaginal pH and flora may dispel the reluctance of some patients to proceed with therapy. However, if it appears that menstruation is a major barrier to cooperation, it is better

to agree to the postponement of treatment rather than risk noncompliance.

Even when treatment has been optimal, the tendency exists for some infections to recur. Patients should be counseled about this possibility and informed about the nature of resistance. This can minimize the development of negative feelings about themselves, their therapy, or their physicians. Similarly, women must be instructed to continue therapy even after achieving symptomatic relief. This is vital, because many currently available agents provide relief within hours of initial use, and symptomatic relief does not necessarily equate with ultimate treatment success.

Therapeutic compliance is also enhanced when patients trust their physician and his or her staff. Women who develop confidence in the skills of the health-care team to provide a correct diagnosis and appropriate treatment are more likely to comply with the recommended regimen. Also, the more patients trust their physicians, the less likely they are to be influenced by family or friends who may have had a negative experience with similar therapeutic regimens. This trust can be fostered through displays of mutual respect, frankness, concern, and willingness to impart information and answer questions. Recent studies have shown that patients who are encouraged to ask questions of their physician not only do so but feel less anxious about their visit, are in better control of matters, and are more satisfied with both the visit and the information they received.6-9

Printed materials can also play an important role in promoting compliance because they allow patients an opportunity to review relevant information at their leisure. Moreover, these educational adjuncts enhance the perception of quality care.7

Finally, it is important to inform patients that despite the best efforts of all parties, vulvovaginitis may recur. When this occurs, it is the physician's responsibility to determine if faulty compliance, microbial resistance, or some other factor is to blame. Follow-up visits for second treatment should include continued patient education to help decrease the chances for noncompliance.

Bacterial vaginosis: Current review with indications for asymptomatic therapy

Jessica L. Thomason, MD, Sheldon M. Gelbart, PhD, and Nancy J. Scaglione, RNC, OGNP Milwaukee, Wisconsin

Bacterial vaginosis is a definable clinical entity whose exact origin is unknown. A shift in normal vaginal flora from aerobic, predominantly but not exclusively lactobacilli, to a predominantly anaerobic flora characterizes the condition. More than one half of all women with bacterial vaginosis have no symptoms. The condition is not entirely benign. The potentially pathogenic bacteria present in the vagina in large numbers place these women at risk for postoperative morbidity and adverse obstetric outcome. Sexual transmission has not been proved, but therapeutic cures sometimes require that patient and partner be treated simultaneously. Recommended therapy is with metronidazole or clindamycin and must be given for 7 days for maximal effectiveness. Recurrence of disease can be a problem. (AM J OBSTET GYNECOL 1991;165:1210-7.)

Key words: Vaginosis, vaginitis, vaginal flora, metronidazole, clindamycin

Bacterial vaginosis is currently the most prevalent infectious cause of vaginitis.1 The condition is characterized by a profuse, malodorous vaginal discharge, but more than one half of patients with demonstrable signs have no symptoms.2 Bacterial vaginosis has been known by various names. Before 1955, all types of vaginitis not caused by trichomonads, yeasts, or gonorrhea were called "nonspecific vaginitis." Gardner and Dukes^{8, 4} recognized that the condition was a specific entity, which they named Haemophilus vaginitis, and they believed that it was caused by a specific bacterium, Haemophilus vaginalis. In time the bacterium could not be considered taxonomically Haemophilus, because it had no absolute requirement for hemin, and thus it became Corynebacterium vaginale.5 The organism was moved eventually to a new genus, Gardnerella.6 It became evident over time that Gardnerella was not the only etiologic cause of bacterial vaginosis, largely because of the inability to eliminate Gardnerella in patients who were cured and its isolation from vaginal secretions in many women without bacterial vaginosis.7-9 Names for the condition reflecting the changing taxonomy of the bacterium were discarded: Haemophilus vaginitis, Corynebacterium vaginitis, and Gardnerella vaginitis.

Attention turned to anaerobic flora that were associated with bacterial vaginosis. ¹⁰ Anaerobic bacteria and not *Gardnerella* produced enzymes that were responsible for the distinct fish-like odor associated with the

condition. Anaerobes produce aminopeptidases, which break down proteins into amino acids and decarboxylases, which convert amino acids and other compounds into amines; that is, decarboxylation of ornithine (a metabolite of arginine) yields putrescine, decarboxylation of lysine yields cadaverine, and decarboxylation of betaine (a metabolite of choline) yields trimethylamine. 11. 12 Recognition of the role of anaerobes led to the syndrome name of anaerobic vaginosis. 15 Eventually the current designation, bacterial vaginosis, was agreed on by international convention. 14

Microbiology of bacterial vaginosis

The normal vaginal ecosystem is very complex. The predominant bacterial flora are lactobacilli, but a large variety of both aerobic and anaerobic bacteria can also be present, many of which are associated with bacterial vaginosis when found in increased numbers. ¹⁵⁻¹⁸ For this reason, taking a vaginal culture is not a clinically useful diagnostic procedure. The numbers of bacteria in the normal vaginal ecosystem are 10⁵ to 10⁶/gm of secretion but in bacterial vaginosis are greatly increased to 10⁹ to 10¹¹/gm of secretion. ^{13, 19}

The cause of this shift in the vaginal ecosystem of women with bacterial vaginosis is not known. Normally occurring lactobacilli, especially the hydrogen peroxide—producing strains, become less evident.²⁰ Aerobic bacteria that produce succinate synergistically allow prolific growth of anaerobes.²¹ A single bacterium that inhibits lactobacilli and produces succinate to initiate the anaerobic overgrowth has not been identified; therefore *Gardnerella*, various anaerobes, and possibly genital mycoplasmas may have a role in the development of the full-blown syndrome.

Symptomatic college populations	~70
Eschenbach	15%
Amsel	24%
Private physician populations	~ 170
Hill	16%

Incidence and risk factors

The incidence of bacterial vaginosis varies in different populations (Table I). Older studies showed rates of 30% to 45% in reproductive-age women in varied clinical settings, including sexually transmitted disease clinics, student health clinics, and private practice; the highest rate, 45%, was reported by Gardner et al.22 in women attending private practice. Modern reviews show a wide diversity of incidence, probably resulting from more exacting objective criteria used to diagnose the condition in women without symptoms. Rates in Sexually Transmitted Disease clinics range from 33% to 64%.1, 23-25 Rates in prenatal or obstetric clinics vary from 10% to 26% (Thomason, unpublished data).26.27 Eschenbach et al.1 reported a 15% incidence in a gynecology clinic in which college students saw a physician because of complaints of the lower genital tract but only a 4% rate in an asymptomatic college student population. Rates of 23% to 29% have been reported in other gynecology or family planning clinics.2, 28 However, lower rates have been reported in women seeking health care from private physicians (16%).27

A major risk factor for bacterial vaginosis is the use of an intrauterine device. 29-33 Barbone et al. 34 associated the number of different sexual partners within the month before examination as a risk factor for bacterial vaginosis. Other probable risk factors (e.g., age, smoking status, abnormal Papanicolaou smears, days of menstrual flow, age of menarche, years since menarche, use of a diaphragm, lifetime number of sexual partners, and rape) have not been associated with bacterial vaginosis. 29, 30, 35, 36

Sexual transmission

It is not clear whether bacterial vaginosis is sexually transmitted. The literature provides evidence supporting both sides of the argument (Table II). Several authors have shown that bacteria associated with bacterial vaginosis, namely, Gardnerella, Mycoplasma, and Mobiluncus, can be recovered from urine and urethral scrapings of the male partners of women with bacterial vaginosis.4, 30, 37-42 However, the organisms do not appear to persist in men. An epidemiologic study searching for a possible reservoir or mode of transmission of the bacteria normally associated with bacterial vaginosis found that all such organisms could be isolated from the rectum in as many as 62% of women with bacterial vaginosis but only in about 10% of women without the disease.42 Holst also reported finding such organisms in the rectums of men and children. Studied organisms were recovered from the urethra or penile coronal sulci only in about one fourth of male consorts of women with bacterial vaginosis. After 2 weeks of condom use, only Mycoplasma hominis could be recovered from the urethra of one man. This study³⁰ supported earlier work in which Mobiluncus species were isolated from either the vagina or rectum of 29 (85%) of 34 women with bacterial vaginosis, which strongly suggests that the rectum may be a reservoir for this organism.

However, the role of the man as a reservoir cannot be ruled out from these studies, especially because a man may be recolonized as a result of unprotected intercourse with a different partner. Vejtorp et al.43 and Moi et al.44 found no beneficial effects on cure rates when partners of women having bacterial vaginosis are treated.43,44 However, criticism of such studies reports that failure was inevitable because of the use of tooabbreviated treatment regimens or because of a poor choice of antibiotic. Treatment of both patient and partner for a longer time span results in significantly higher cure rates, which suggests some relationship between bacterial vaginosis and sexual transmission.⁴⁵

Another argument against sexual transmission is the finding by Bump and Bueschling⁴⁶ that bacterial vaginosis could be detected in 12% of virginal women. This must be weighed against the report by Amsel et al.²⁹ of a university population in whom bacterial vaginosis was found in 69 (23.5%) of 293 sexually experienced women and in none of 18 who were virgins.

Evidence of sexual transmission comes from studies that show a strong correlation between the numbers of sexual partners 30 days before examination in women with and without bacterial vaginosis, greater than five lifetime sexual partners, and the decreased rates in monogamous couples. ^{27, 34, 47} Briseldon and Hillier ⁴⁸ recently showed that longitudinal biotyping of *Gardnerella* reveals women who acquire bacterial vaginosis are more likely to have *Gardnerella* strains with different biotypes than women who still had normal vaginal flora at their follow-up visits. This suggests that the *G. vaginalis* isolates recovered from women represent newly acquired strains rather than overgrowth of previously colonizing biotypes. Unequivocal sexual transmission of bacterial vaginosis remains to be proved.

Diagnosis

Malodorous vaginal discharge is the only symptom consistently reported by women having bacterial vaginosis. However, more than one half of all women with bacterial vaginosis may be entirely without symptoms, just as women may be without symptoms with infections caused by *Chlamydia trachomatis* or gonorrhea.⁴⁹

The clinical criteria developed by Amsel et al.²⁹ have become the reference standard for clinical signs of bacterial vaginosis. This group incorporated the observations of Gardner and Dukes,⁴ who described (1) the clue cell, (2) homogeneous discharge that adheres to but is easily wiped from the vaginal walls, and (3) an elevated vaginal pH, with the observation of Pheifer et al.³⁷ who developed (4) the potassium hydroxide test for volatile amines. The presence of any three of these four signs is considered diagnostic for bacterial vaginosis.

Recent studies of Thomason et al.⁴⁹ and Ceddia et al.⁵⁰ have shown that use of only two of the four objective signs (e.g., clue cells and positive amine test) allows accurate and rapid diagnosis of bacterial vaginosis without sacrificing sensitivity. The amount and physical appearance of vaginal discharge are difficult to evaluate objectively.⁵¹ The amount of discharge in women with bacterial vaginosis generally does not exceed that normally seen and can be affected by douching or recent intercourse. Vaginal pH is considered the most sensitive but least specific characteristic of the Am-

sel criteria, because it can be influenced by many factors, such as vaginal bleeding, douching, and recent intercourse.⁵¹ Clue cells, squamous vaginal epithelial cells so covered with attached bacteria that the borders are obscured, are the most sensitive and specific sign of bacterial vaginosis, especially when seen in wet mount preparations of vaginal secretion.⁴⁹ However, the use of clue cells as the single diagnostic criterion is limited to skilled microscopists.

Culturing for Gardnerella to make the diagnosis of bacterial vaginosis, although heavily relied on by earlier investigators, has in subsequent times proved worthless.^{1,52} Using specially designed media to enhance isolation,⁵³ it has been possible to find G. vaginalis in more than 50% of women with no bacterial vaginosis.¹ Even when Gardnerella is isolated in larger quantity, the positive predictive value for having bacterial vaginosis is only 40%.¹ Culture of Gardnerella is not useful for "test of cure," because many women without bacterial vaginosis have positive test results for this organism after effective treatment.⁵¹

Mobiluncus is a fastidious, curved, anaerobic motile rod more useful as a marker for disease than is Gardnerella.⁵⁴ The organism is highly specific for bacterial vaginosis but can be difficult to identify in wet mount examination of vaginal secretions because of its physical size.⁵⁵ Because of the difficulty in isolating this organism by culture techniques, genetic probe and monoclonal antibody immunofluorescent methods of identification have been developed.⁵⁶⁻⁵⁸ Virtually all women having Mobiluncus species identified in vaginal secretions have bacterial vaginosis.²³ However, not all women with bacterial vaginosis have Mobiluncus species as part of their abnormal vaginal bacteriology.

Bacterial vaginosis can be diagnosed by Gram's stain of vaginal secretions. Two methods of interpretation have been developed. The newer method of Nugent et al.⁵⁹ is more specific for bacterial vaginosis than the older method of Spiegel et al.⁶⁰; however, neither considers clue cells in its methodology. It is possible to recognize clue cells on Gram's stain. Combining the presence of clue cells with diminished lactobacilli morphotypes on Gram's stain may further simplify interpretation of such vaginal smears (Thomason JL, Gelbart SM, Osypowski PJ, unpublished observations). Clue cells and changes in flora can also be identified on Papanicolaou smears,^{61,62} but this has not proved as specific for bacterial vaginosis as other methods of identification.⁶³

Other rapid diagnostic methods for the identification of women having bacterial vaginosis have been developed but are largely relegated to research purposes. These tests are based on detection of bacterial metabolic products in vaginal secretions of women with bacterial vaginosis. Gas-liquid chromatographic analysis to detect succinic acid,10 thin-layer chromatography for the determination of putrescine and cadaverine,11 and enzymatic analysis for proline aminopeptidase2. 64 are three such tests.

Sequelae

Although bacterial vaginosis frequently produces few patient symptoms, serious infectious sequelae occur in women who have this disease. The following bacteria associated with bacterial vaginosis are known to be potential pathogens: Prevotella bivia, Prevotella disiens, Prevotella melaninogenica, G. vaginalis, and M. hominis. In addition, patients with bacterial vaginosis have greatly lowered vaginal tissue redox potential and elevated vaginal pH, both conditions known to be associated with increased infective potential.65 In addition, enzymes and metabolic by-products of the abnormal bacterial flora significantly impede normal white blood cell response to infection.

In the patient with gynecologic disease, bacterial vaginosis is associated with laparoscopically proved pelvic inflammatory disease, urinary tract infections, endometritis, and postoperative vaginal cuff infections. 35, 66-70 First suggested by Westrom 66 and confirmed by Paavonen et al.67 laparoscopically proved pelvic inflammatory disease is rarely seen if the vaginal secretions show no clue cells and if lactobacilli are the predominant flora. Colonization of the vaginal introitus as seen in bacterial vaginosis increases the risk of urinary tract infections. 85,68 Faro et al.71 relate bacterial vaginosis to postoperative infections in both obstetric and gynecologic settings. Cervical dysplasia has also been linked epidemiologically but not causally with bacterial vaginosis (relative risk 2.0).71a

In patients with obstetric disease, bacterial vaginosis is related to preterm labor, premature rupture of membranes, chorioamnionitis, and postcaesarean and postpartum endometritis.71-74 Literature before 1989 was reviewed by Martius and Eschenbach,75 who discussed how phospholipase A2 production could trigger the prostaglandin cascade leading to labor. Some bacteria associated with bacterial vaginosis are strong phospholipase A2 producers.76 McGregor et al.77 defined multiple associations between various maternal reproductive tract infections and other known noninfectious risk factors and obstetric outcomes. With bacterial vaginosis as a single risk, the relative risk of preterm labor was 2.6 times normal. However, when bacterial vaginosis was combined as a risk with the finding of Mobiluncus on Gram's stain or the isolation of Mycoplasma from vaginal flora, relative rates of preterm birth increased sixfold from normal rates. When combining the wellknown risk of a history of a previous preterm birth with other infectious risks, population-attributable risks for preterm birth reached 71%.

Treatment

Before discussing the therapeutic options, it is important to determine which patients with bacterial vaginosis should receive medical treatment. It is generally agreed that patients who do have symptoms should be treated to alleviate discomfort, but more than one half of patients with bacterial vaginosis do not have symptoms. The Centers for Disease Control recommendation that patients without symptoms should not be treated does not consider the implications of the more recently published studies documenting serious infectious sequelae.78 The explosion of papers on bacterial vaginosis in recent years and the question of sexual transmission of this disease make such guidelines difficult to formulate. Risk from therapy versus benefit to patients must always be weighed. When risk is low from antibiotic therapy and only the patient must be considered, recommendations are easier to formulate. However, when both a mother and an unborn infant are involved with therapy, guidelines are more difficult to recommend. Currently data from sequelae are strong enough to warrant treatment without hesitation in some asymptomatic populations.

Asymptomatic gynecologic patients with bacterial vaginosis who are about to undergo outpatient ambulatory invasion procedures, such as endometrial biopsy, hysteroscopy, hysterosalpingography, or placement of an intrauterine device, should be treated before these procedures. Women with bacterial vaginosis scheduled for vaginal or abdominal surgery should also be treated before surgery. We recommend treatment of this population with a full course of therapy and not just a prophylactic dose of antibiotics immediately before the procedure. By reducing the large number of potentially pathogenic bacteria, it should be theoretically possible to reduce the complications of postoperative infections. 79 This is a controversial area because only recently has bacterial vaginosis been proved a risk factor for various postoperative complications. Therefore the modulating effects of preoperative or perioperative prophylactic antibiotics have not yet been proved.

Treatment of obstetric patients who have bacterial vaginosis is more controversial. Patients with premature rupture of membranes or a history of premature labor may benefit from therapy. As elucidated by McGregor et al.,77 the risk of adverse obstetric outcome because of bacterial vaginosis is low; however, when coupled with other factors, the risk becomes great enough to consider strongly treatment of this underlying condition.

Interestingly, Bump et al.80 have demonstrated a high

Table III. Antibiotic therapy for bacterial vaginosis

Effective Metronidazole, 500 mg, orally twice daily \times 7 days Clindamycin, 300 mg, orally twice daily × 7 days Clindamycin 2% intravaginal cream (research) Metronidazole 0.75% intravaginal gel (research) Questionable Ciprofloxacin Amoxicillin/clavulanate potassium Metronidazole, single 2 gm dose Triple sulfa cream Lactate gel Ineffective Erythromycin Tetracyclines Ampicillin Povidone iodine Acetic acid Dienestrol

spontaneous cure rate in some patients without symptoms. For this reason, placebo control groups are recommended for antibiotic effectiveness trials. Antibiotic treatment of bacterial vaginosis can also lead to vulvovaginal yeast infections. 81 Each health care professional should advise patients, whether they do or do not have symptoms, if bacterial vaginosis is found during a pelvic examination. Risks and benefits can be weighed by patients, who should actively participate in the decision about the need for therapy.

Therapy of bacterial vaginosis has recently been reviewed by Hillier and Holmes⁵¹ and by Lossick.⁸² Metronidazole and clindamycin are the most effective antibiotics (Table III). Erythromycin does not work, because macrolide antibiotics are not effective at the acid pH level of the vagina.88 Ampicillin does not work, probably because of poor activity against anaerobes, especially with production of β-lactamases.84 Other newer antibiotics, such as ciprofloxacin85 and amoxicillin/clavulanate,86,87 show some effectiveness but appear to be less efficacious than metronidazole or clindamycin. Ventolini et al.88 have shown that twice-daily douching with various preparations, including povidone iodine and aluminum acetate, does not effectively cure bacterial vaginosis. Povidone iodine, even when inserted as a vaginal pessary twice daily for 14 days, was completely ineffective.89 Other nonantibiotic therapies, including acetic acid gel, dienestrol cream, and yogurt preparations, have not been found to be efficacious; however, a newer lactate gel, studied in Europe, has been reported to have a high cure rate. 90, 91

Metronidazole, when used systemically, should be given for at least 7 days. Metronidazole used in a shorter or immediate 2 gm dose gives lower cure rates both initially and in longer follow-up studies. ⁵¹ However, systemic metronidazole therapy may not be necessary. Intravaginal treatment with 500 mg of metro-

nidazole twice daily for 7 days has been found to be effective. ⁹² Vaginal sponges impregnated with metronidazole have also been shown to be efficacious. ^{93, 94} More recently a metronidazole gel preparation used for 5 days looks promising but is available only through research protocol.

Clindamycin, when used systemically, should be given for 7 days. Although a 300 mg twice daily dose has been found effective, higher cure rates may occur if a three times per day regimen is used (Thomason, unpublished data). Topical administration of clindamycin has also been effective for bacterial vaginosis. A 2% clindamycin cream preparation used once daily in a 5 gm dose has a cure rate of 94%. Longer term (28 to 35 days after therapy) cure rates were in the 90% range. This drug formulation will be marketed in the near future.

Sexual partner therapy

As discussed previously, sexual transmission of bacterial vaginosis has not been proved, but coital transmission of associated microorganisms occurs. This creates a therapy paradox. To date data show no benefit of partner therapy if clinical signs were used to define cures. However, one study using more objective diagnostic criteria demonstrated that treating partners significantly increased cure rates in women. Although current recommendations from the Centers for Disease Control are that routine treatment of sexual partners is unnecessary, women who have intractable disease or recurrent bacterial vaginosis should be counseled about the possible benefit if partners also receive therapy.

Recurrence

Recurrent disease is a serious clinical problem. Hillier and Holmes⁵¹ anecdotally refer to an 80% recurrence rate within 9 months of completion of metronidazole in their studies. Although reasons for recurrence are not understood, they give the following possible explanations: (1) reinfection by a male partner who is colonized with bacterial vaginosis—associated microorganisms; (2) recurrence as a result of the persistence of bacterial vaginosis—associated microorganisms that are inhibited but not killed during therapy; (3) the failure to reestablish the protective *Lactobacillus*-predominant flora after therapy; and (4) the persistence of an unidentified host factor, which makes the woman susceptible to recurrence.

Conclusion

The pathophysiology of bacterial vaginosis remains inexact. The effects of specific antibiotic therapy on the vaginal bacterial population are largely unknown. It has taken decades to define normal vaginal flora and to realize that women having bacterial vaginosis may be

without complaints of vaginal discharge. Earlier studies frequently defined the control population as one "without symptoms." Diagnostic criteria used objectively to identify women having bacterial vaginosis without observer bias continue to be defined. Serious sequelae documenting the predisposition to infectious morbidity in women with this disease have only been identified recently. Trials to show the value of therapeutic intervention in women with and without symptoms can now be justified.

Trichomoniasis: Trends in diagnosis and management

Joseph G. Lossick, DO, MS,† and Howard L. Kent, MD

Atlanta, Georgia, and Philadelphia, Pennsylvania

The mainstay of the diagnosis of trichomoniasis has been the saline vaginal wet preparation. With a less than desirable sensitivity, the wet preparation may be replaced in the near future by newer methods employing monoclonal antibodies, such as the enzyme immunoassay, which has the potential to become an in-office procedure. The direct fluorescent antibody test also represents an advance in laboratory diagnosis. However, until the sensitivity, specificity, and cost of these newer techniques are defined outside the research arena, the wet preparation will remain the first-line diagnostic tool. Current treatment of trichomoniasis in the United States is with metronidazole, which in repeated or increased dosage can often overcome the organism's resistance to the drug. Other treatments offer little or no chance for cure but may provide some relief of symptoms. Tinidazole (not available in the United States) may be effective in curing refractory cases of metronidazole resistance. Metronidazole treatment during pregnancy should be resorted to only when absolutely essential. (Am J Obstet Gynecol 1991;165:1217-22.)

Key words: Trichomoniasis, wet preparation, Papanicolaou smear, culture, nitroimidazoles, metronidazole

Trichomonas vaginalis is one of the most common organisms causing vaginitis in women worldwide and affects approximately 3 million American women annually.^{1,2} Although the older literature erroneously refers to *T. vaginalis* as a harmless commensal,^{3,4} its role as a pathogen is now universally accepted. For the most

Table I. Comparison of tests for diagnosing trichomoniasis

Technique	Advantages	Disadvantages
Vaginal saline wet mount	Low cost, easy, stat office diagnosis; 100% specificity if motile organisms noted	Low sensitivity by average microscopist (45%-60%)
Stained slide preparation (Papanicolaou smear)	Slide can be fixed and read/reread later; good sensitivity in skilled hands	Imperfect specificity even in skilled hands
Culture	"Gold standard"; 92%-95% sensitivity; can be used for susceptibility studies	Not readily available; more expensive than wet preparation; not a stat diagnosis
DFA	Transportable, stable; 80%-95% sensitivity; fast turnaround diagnosis	Not readily done in clinical setting; more expensive than culture; some false-positive results occur—specificity 99%-99.5%
EIA	Transportable, stable; good sensitivity; may be in-office test; selectively stains organism	Sensitivity lower than with culture; sensitivity and specificity need more definition; required costs and expertise?
Latex agglutination	Stat diagnosis; more sensitive than wet preparation (≤95%); can be run in batches	Lower sensitivity than culture; sensitivity and specificity need more definition; unknown costs; equivocal agglutination endpoint; not available in United States

part, *T. vaginalis* is considered to represent a classic venereal disease, despite its slight potential for non-venereal transmission.⁵⁻⁷

As in other infectious diseases, the diagnosis of trichomoniasis has been greatly influenced by the development of monoclonal antibody laboratory tests. A review of the various diagnostic procedures for making the clinical diagnosis of trichomonal vaginitis follows.

Diagnosis of trichomoniasis

Six tests are currently available to the clinician for determining the presence of vaginal trichomonads (Table I).

Vaginal saline wet mount. In use for more than 150 years and long the mainstay for the diagnosis of trichomoniasis, the saline wet mount of vaginal secretions has only recently been subjected to scrutiny as to its sensitivity and specificity. Approximately 60% to 70% of infections will be detected with this method.2 However, when compared to sensitivity of culture, sensitivity of the wet mount ranges from 45% to 60% in the hands of the average microscopist and from 60% to 92% in those of a highly trained researcher. Also, there is minimal quality assurance of interpretation of results of this procedure. In addition to the limited sensitivity of this test, another disadvantage is the need for immediate microscopic evaluation. As a plus, this test is inexpensive and has a virtual 100% specificity when motile organisms are identified.

When inoculum is adequate, *T. vaginalis* is easily identified by its pear shape, five flagella, and peculiar twitching motion. It can be seen, with its characteristic undulating flagella, darting between other nonmotile cells. Unfortunately, a negative wet mount in a patient with

acute florid vaginitis does not rule out trichomoniasis, since this organism can produce a soluble exotoxin that can cause inflammatory tissue reaction out of proportion to the number of organisms involved.

Stained slide preparation (Papanicolaou smear). Clinicians have long accepted the diagnosis of "trich" by the cytologist as part of their interpretation of Papanicolaou smears, and this has essentially been a "nocharge" benefit of routine cytologic procedures. One advantage of stained slide preparations like the Papanicolaou smear is that permanent preparations can be kept and reviewed later. Unfortunately, as with the vaginal wet mount, the specificity and sensitivity of this procedure have been determined only in the past decade. In an experienced cytologist's hands, this test has a similar sensitivity to that of the wet mount and a 99% specificity. Among less skilled technicians, however, its specificity approximates 95% to 99%.8 It is important that the cytologist maintain strict standards for objective determination of Trichomonas in the Papanicolaou smear.

As with the wet mount, there has been little quality assurance of Papanicolaou smear interpretations until recently, when some laboratories undertook concomitant culturing of vaginal smears as a reference check. Centers for Disease Control (CDC) studies have found that without routine culturing, both clinicians and technicians have no way of knowing if the sensitivity or specificity of diagnostic tests in their laboratories is appropriate. Routine culturing can provide cytologists essential information to improve their diagnostic skills.

With cytologic staining, as with any diagnostic procedure, one must remember that the positive predictive value will increase as the disease frequency increases in the population. Also, stained Papanicolaou smears, which are used mainly for screening women who have no symptoms, will exhibit sensitivity and specificity that are less than when employed as a diagnostic test in patients with symptoms. Since the load of the infectious agent is higher in the patient with symptoms, this and the wet mount will demonstrate a greater sensitivity in those women who have symptoms. Therefore, unless there is a high index of suspicion for trichomoniasis, preliminary results of cytologic tests must be confirmed before treatment is initiated.

Despite some putative improvements in staining procedures (acridine orange, Romanovsky, Diff-Quick, Harleco, Herstal, Belgium) and the development of dark-field and phase-contrast microscopy, none of these techniques has been used on a widespread basis.

Culture methodology. Possessing the ability to amplify the number of trichomonads in the original specimen and a high degree of sensitivity (92% to 95%), culture techniques are regarded as the "gold standard" in the diagnosis of *Trichomonas* infection. An added benefit is the ability to perform susceptibility studies on specific strains by use of these culture techniques.⁴

Unfortunately, routine diagnostic culture is not readily performed in the United States. Whereas many types of culture media are available, Diamond's TYM (tripticase, yeast, maltose) is regarded as the superior medium. Since trichomonads grow best under anaerobic conditions, the incorporation of 0.05% to 0.1% agar into the medium allows for superior growth because it reduces the diffusion of oxygen into the medium.⁴

The down side of culture techniques is threefold: the relative nonavailability of the media, the greater cost of the procedures, and the need to allow 3 to 7 days to elapse before the diagnosis is confirmed. The latter factor might cause unacceptable delay in the initiation of therapy.

Direct immunofluorescence assay (Integrated Diagnostics, Calif.). Available for more than 2 years as a result of the development of monoclonal antibodies, direct fluorescent antibody staining (DFA) has been found to be more sensitive than the wet mount (80% to 90%), although less so than culture.9, 10 In addition to sensitivity, its advantages include more rapid diagnosis than culture (usually ≤1 day) and stability for up to 7 days, which allows for transportation to a laboratory. Among its disadvantages are the requirement for a fluorescent microscope and a trained microscopist, greater expense than that for culture, and the occasional false-positive result (specificity rate, 99% to 99.5%). Since DFA is a relatively new technique, sensitivity and specificity data are available only from research settings where trained technicians are performing this test. Whether DFA will be as accurate when it becomes translated to the diagnostic marketplace for volume testing cannot be ensured.

Direct enzyme immunoassay. Like the DFA, the monoclonal-based enzyme-linked immunoassay (EIA) offers the advantages of transportability along with sample stability and a greater sensitivity than for the wet mount.11, 12 Similar to DFA, these sensitivity data are generated from research settings and remain to be defined in the clinical or commercial laboratory setting. One major advantage of EIA over DFA is its promise of becoming an in-office procedure that can possibly replace the wet preparation, since only a light microscope is required for interpretation. EIA selectively stains the organism on the basis of monoclonal antibody tagging of the outer membrane protein; however, this ability is somewhat limited in certain geographic areas because of the distribution of aberrant T. vaginalis strains that do not tag readily with the antibody. Because it is a nonamplified assay, the sensitivity of EIA is less than that of culture. Other unanswered questions about EIA are the eventual cost in the clinical setting and the level of expertise required by personnel for accurate results.

Latex agglutination test (Mercia Diagnostics, Ltd., Guildford, Surrey, United Kingdom). Similar to the DFA, this test has a higher sensitivity (95%) than the wet preparation.13 This 5-minute test was basically designed to replace the wet preparation as an easy-toperform test providing immediate results. Cotton swabs containing vaginal secretion are eluted by immersion and agitation in 500 ml glycine-buffered saline. The test is performed by mixing 30 µl eluate with 30 µl of the test and control latex preparations. The mixtures are read on a black slide and checked for agglutination over a 2-minute period. In addition, batch runs are also possible because testing can be delayed. Remaining unanswered questions about this test concern its sensitivity and specificity in the clinical setting and its cost. In a preliminary study of this test by Joseph Lossick, a positive endpoint was difficult to define, with the agglutination often being equivocal. Moreover, at least one batch of reagent supplied by the company produced significant amounts of nonspecific agglutination. With further modifications, the latex agglutination test holds some diagnostic promise for the future. Currently, this test is not commercially available in the United

In summary, these new technologies promise improved accuracy for the diagnosis of trichomoniasis, but they are not likely to replace the wet preparation in gynecologic practice, since it is still a reasonably accurate, simple, and inexpensive procedure. Before physicians abandon the wet preparation, further refinements are needed for some of these assays and the following four issues need to be addressed more fully: (1) definition of the sensitivity and specificity of all new

and traditional diagnostic methods in the clinical arena; (2) quality assurance of clinical and commercial laboratory performance; (3) diagnostic reliability in male patients; and (4) cost-effectiveness of each new diagnostic procedure.

Diagnostic axioms. Inflammatory cells found in the cervical or vaginal secretions should prompt a search for trichomoniasis and other sexually transmitted disease, such as chlamydia, gonorrhea, or herpes. Often, a physician can fine-tune his or her skills in diagnosing *Trichomonas*-based vaginitis by the color of the vaginal epithelium when backup wet preparations and cultures are used as learning tools.

When inflammatory vaginitis exists in the absence of a positive wet preparation, a more sensitive diagnostic procedure such as culture should be used. Because patients without symptoms usually have a low level of *Trichomonas* in the inoculum, other tests, such as DFA and EIA, will probably have a lower sensitivity level than in patients with a positive wet preparation. Culture, on the other hand, should identify the organism if between 1 to 10 are present in the initial specimen.

Incidental Papanicolaou smear findings consistent with trichomoniasis must always be confirmed with wet preparation or other diagnostic procedures if the likelihood of infection is low or unknown, in any given patient.

Treatment of trichomoniasis

Local preparations. Before the 1960s, when systemic metronidazole was first introduced, trichomoniasis generally persisted throughout reproductive life because of the multifocal nature of the disease. Available treatments at the time were local and primarily palliative, offering some symptom relief but only rare cure. Among local medications used were surfacants, pH-lowering agents, and trichofuron. Although therapeutic efficacy was never well defined, available data suggest success in only about 20% to 40% of cases.

Surfacants were designed to "explode" the organisms by creating dramatic osmotic pressure changes that altered the cellular membrane. Also, pH-lowering agents were used in an attempt to make the vaginal environment inhospitable to *T. vaginalis* growth. Clinical cure rates for surfacants and pH-lowering agents ranged from 20% to 40%, but the accuracy of these reported rates is questionable because cultures were used only in the laboratory setting.

Trichofuron, in the form of suppositories or powder insufflations, was used up until the 1960s. Daily powder insufflations were messy for both the patient and the practitioner, cure rates were poorly defined, and patient compliance was minimal.

More recently available local agents include clotrimazole, povidone-iodine, and nonoxynol-9. Clotrimazole was recommended by the CDC as an alternative treatment to metronidazole only a few years ago, but unfortunately, this recommendation was based on three poorly designed studies that claimed cure rates between 60% and 85%. However, broad clinical use after the CDC recommendation revealed symptom relief only, without definitive cure. Likewise, povidone-iodine, which is currently recommended as an alternative treatment in patients for whom metronidazole is contraindicated, produces effective symptom relief but without definitive cure. Nonoxynol-9 shows in vitro efficacy against *T. vaginalis* and also provides symptom relief, but cures appear to be rare.

The nitroimidazoles. The introduction of the nitroimidazoles in 1960 for the systemic treatment of trichomoniasis dramatically changed the therapeutic approach to this infection. Metronidazole is the only nitroimidazole available in the United States, but worldwide the list of similar agents is long—nimorazole, tinidazole, ornidazole, secnidazole, carnidazole, and misonidazole.

Standard treatment with metronidazole is one 250 mg dose, given orally three times a day for 7 consecutive days. Although the efficacy of a single 2 gm oral dose has been confirmed in women,¹⁵ lower efficacy is reported in men.¹⁶ Worldwide, a 1.5 gm dose is usually adequate with more active drugs such as tinidazole. Local treatment with metronidazole suppositories has been tried, but cure rates of only 30% to 60% were reported. This finding is not surprising because trichomoniasis is a multifocal infection involving the Skene's glands, the vaginal epithelium, Bartholin's gland, and the urethra.

Metronidazole resistance. When metronidazole was first introduced, cure rates approximated 95%; but within 2 years of its introduction, the first case of metronidazole resistance was reported in Canada. Nitroimidazole resistance has been reported in most areas of the world and, in recent years, the prevalence of metronidazole resistance seems to be increasing.^{17, 18}

Although methods for determining the sensitivity of *T. vaginalis* are not standardized, the testing procedures developed at the CDC on more than 300 isolates have led to the conclusions that there are four levels of metronidazole resistance in *T. vaginalis* infections—marginal, low, moderate, and high. Moreover, most of the resistant strains have either marginal or very low resistance. Thus metronidazole resistance is not an "all or nothing" phenomenon.

Marginal resistance occurs in one of every 50 to 75 cases, but only one half of these cases will require retreatment. Low and moderate resistance may occur in one out of 200 to 400 cases, and very high levels of resistance occur in approximately one in 2000 to 3000 cases. Fortunately, most cases of nitroimidazole-resis-

tant *T. vaginalis* are readily cured with larger doses of the drug. High-level resistance is, however, very difficult to treat, usually requiring long-term metronidazole therapy with high doses, which may be associated with toxicity.

Treatment regimens that have been found to be curative at different levels of resistance are shown in Table II. Approximately 85% of marginally resistant cases will be cured by retreatment with the standard dose, especially if it is repeated soon after the initial failed treatment, when the organism load is lower. In cases of low-level resistance, easy cure is usually achieved with slightly increased dosage levels. In cases of moderate resistance, a 2.5 gm divided dose for 7 to 10 days will usually cure the infection.

The proper approach to the management of patients with high-level resistance is unclear, since doses of metronidazole required for cure make patients ill. Toxicity includes but is not limited to gastrointestinal upset, metallic taste, glossitis, stomatitis, urticaria, vertigo, and more significantly, convulsive seizures and peripheral neuropathy.

An effective alternative to high-dose oral metronidazole in a highly refractory case was recently reported by Dombrowski et al., who treated a patient with 2 gm of intravenously administered metronidazole every 6 to 8 hours for 3 days. Mild nausea was reported only after the last dose. It is theorized that the side effects of metronidazole are related to the accumulation of the hydroxy metabolite, which occurs around the third or fourth day of treatment—the peak time for most side effects. Although the evidence is anecdotal, neurotoxicity appears to be a consistent problem when high-dose treatment exceeds 3 or 4 days.

Combined oral/vaginal treatment. A recent report of two cases suggests that combination oral/vaginal treatment with metronidazole may be a therapeutic alternative in refractory cases. In this report, 500 mg metronidazole three times a day, in addition to a 1 gm metronidazole suppository three times a day and a 3% acetic acid vaginal lavage two times a week for 2 weeks, successfully eradicated *T. vaginalis* infection: Given the 20% to 30% systemic intravaginal absorption of metronidazole, these cases were probably cured because vaginal treatment contributed to the systemic drug load.

Tinidazole. Although cross-resistance with the nitroimidazoles is the rule, it is often incomplete and many metronidazole-resistant infections resulting from T. vaginalis can be cured with increased but nontoxic doses of tinidazole. In fact, 65% to 70% of T. vaginalis strains highly resistant to metronidazole show increased susceptibility to tinidazole. At the CDC, five documented cases of infection not cured with ≥ 3 gm metronidazole daily for 14 days were cured with tinidazole

Table II. Metronidazole treatment of refractory vaginal trichomoniasis

Resistance level	Metronidazole regimen
Marginal	Retreatment with standard dose
Low	2 gm daily for 3-5 days
Moderate	2-2.5 gm in divided doses daily for 7-10 days
High	3-3.5 gm dailý for 14-18 days
High (alternate therapy)	2 gm intravenously every 6-8 hr for 3 days

at 2 gm daily for 7 to 14 days. Unfortunately, tinidazole, although available in Canada and elsewhere, is not yet available in the United States.

Treatment of trichomoniasis in pregnancy. Because metronidazole crosses the placenta and has been associated with experimental mutagenicity in bacterial systems and carcinogenicity in animals, there has been reticence on the part of clinicans to use metronidazole during pregnancy.²¹ Although data from short-term evaluations suggest that there is no risk of congenital defects when metronidazole is used during pregnancy,²² to date, no study has investigated the oncologic potential of this DNA-acting drug in exposed fetuses. Although one paper suggests the possibility of a metronidazole-induced teratogenic effect,²⁵ this might be coincidental, since other human and animal studies do not support this conclusion.

A recent study suggests that the carriage of *T. vaginalis* is independently associated with low birth weight infants (157 gm or lighter) and premature rupture of the membranes.²¹ This study confirms anecdotal evidence that has linked urogenital trichomoniasis with poor gestational outcomes. However, questions still remain as to whether *T. vaginalis* is the sole etiologic agent associated with premature rupture of membranes or low birth weight, or whether the anaerobic flora of other sexually transmitted diseases that often accompanies trichomoniasis is responsible.

Unfortunately, there are no effective drugs to treat *T. vaginalis* during pregnancy. Treatment of pregnant women who have symptoms might initially consist of 100 mg clotrimazole suppositories daily at bedtime for 2 weeks, which appears to cure about 50% of infections. Caution dictates avoiding use of metronidazole in the first trimester, but a single 2 gm dose may be acceptable in the second or third trimester if prenatal intervention is absolutely necessary and initial treatment attempts fail.

Vulvar vestibulitis syndrome: An overview

Stanley C. Marinoff, MD, MPH, and Maria L. C. Turner, MD Washington, D.C.

Vulvar vestibulitis syndrome is a constellation of symptoms and findings involving and limited to the vulvar vestibule that consists of: (1) severe pain on vestibular touch to attempted vaginal entry, (2) tenderness to pressure localized within the vulvar vestibule, and (3) physical findings confined to vulvar erythema of various degrees. Histopathologic findings are consistent with a chronic, nonspecific inflammatory response that is occasionally associated with metaplasia of the minor vestibular glands. The cause is likely multifactorial, and to date the syndrome has been seen in association with subclinical human papillomavirus, chronic recurrent candidiasis, chronic recurrent bacterial vaginosis, chronic alteration of vaginal pH, and the use of chemical and destructive therapeutic agents. Therapy is directed at elimination of these symptoms. When symptoms are unrelieved, a surgical approach consisting of vestibulectomy with vaginal advancement has a high rate of success. (AM J OBSTET GYNECOL 1991;165:1228-33.)

Key words: Vulvar vestibulitis, dyspareunia, human papillomavirus, candidiasis, bacterial vaginosis, vaginal pH

One of the most perplexing problems faced by the practicing gynecologist is that of the patient with chronic vulvar burning and irritation. At the 1983 Congress of the International Society for The Study of Vulvar Disease (ISSVD), the terms "vulvodynia" and the "burning vulva syndrome" were introduced. Vulvodynia was defined as "chronic vulvar discomfort, especially that characterized by the patient's complaint of burning (and sometimes stinging, irritation or rawness)." Further, the ISSVD consensus was that "vulvodynia should be differentiated from pruritus vulvae, which is associated with chronic itching. Vulvodynia can have multiple etiologies, and use of this term for a patient's problem should prompt a thorough diagnostic evaluation." Although vulvodynia by definition means vulvar burning, the spectrum of pain in the vulva area is often described by patients as burning whether elicited by touch or other stimuli. Thorough diagnostic evaluation has led to the establishment of various subsets of vulvodynia, one of which is the vulvar vestibulitis syndrome. This article presents the authors' perspective on this syndrome.

A constellation of symptoms involving and limited to the vulvar vestibule of: (1) severe pain on vestibular touch or attempted vaginal entry, (2) tenderness to pressure localized within the vulvar vestibule, and (3) physical findings confined to vulvar erythema of various degrees has been designated the "vulvar vestibulitis syndrome."²

The pain may be described as sharp, burning, or a sensation of rawness. Although the sine qua non is introital dyspareunia, the pain may also be elicited on tampon insertion, biking, or wearing tight pants. The present authors first introduced the concept of grading the severity of dyspareunia, which is important in choosing therapeutic options and in evaluating their results. The levels of dyspareunia are a reflection of the patient's subjective perceptions and are described in Table I.

The erythema seen with this syndrome may be diffuse or focal and may be localized around the orifices of the major (Bartholin's, Skene's, or periurethral) or minor vestibular glands or at the fourchette (Figs. 1 through 3, pp. 1224 and 1225).

Historical perspective

Vulvar vestibulitis syndrome has been described by various terminology such as "focal vulvitis" or "vestibular adenitis" for more than 100 years. Skene,3 in his classic Treatise on the Diseases of Women, described a "hyperesthesia" of the vulva that mimics this syndrome. A few years later, Thomas and Munde⁴ described a similar condition., The condition was then forgotten for the next 30 years until 1928, when Kelly⁵ described tender red spots on the vestibule that made intercourse intolerable. In 1942 Hunt⁶ identified the minor vestibular glands but made no connection between them and the syndrome. It was not until 1976 that Pelisse and Hewitt⁷ reintroduced the subject when they described pain with intercourse associated with erythematous vulvitis and plaques in a report of 30 cases. In 1978 Robboy et al.8 described the minor vestibular glands, their origin, and their presence in specimens at autopsy. The association of the female equivalent of plasma cell balanitis of Zoon and a similar entity in women was reviewed by Davis

et al.9 in 1983. They called the condition "vulvitis circumscripta plasmacellularis" and noted the rarity of this condition. However, their description of the patient's symptoms and the accompanying photograph are classic of the vulvar vestibulitis syndrome. In the same year, Woodruff and Parmley10 reported on 15 patients with dyspareunia and physical findings limited to the vestibule. They first described an operative procedure to correct this problem with satisfactory results in 14 of 15 patients treated. The vulvar vestibule as an entity was described by Friedrich,11 who introduced the term "vestibular adenitis." He concurred about the need for a surgical approach but used the carbon dioxide laser. However, in a later paper, 12 a comparison of the results obtained by different management methods showed that surgery was superior. In 1986 Marinoff and Turner¹³ demonstrated that these patients were not allergic to or irritated by common topical therapeutic agents or their vehicles. In an attempt to consolidate the constellation of symptoms (introital dyspareunia, absence of active infection, erythema around the orifices of the minor vestibular glands, and exquisite tenderness to point palpation) manifested by these patients, the term "minor vestibular gland syndrome" was introduced.

In 1987 Friedrich² reviewed 86 patients with similar signs and symptoms. He introduced the term "vulvar vestibulitis syndrome" and suggested its adoption as the standard description of this disorder. All his patients were white, with a median age of 37 years, although the largest number of patients was between age 20 and 30. Data were retrospectively collected on these patients by a questionnaire. Sixty-three percent of responding patients reported having severe and repeated vaginal candidiasis, and 48% reported that they were "allergic" to one or more substances. Surgery led to significant relief in 60% of patients having surgery.

Except for the statistics on surgical success, these figures mirror the current authors' population. Whether the racial makeup reflects an anatomic variation or a social difference is still to be determined. The difference in surgical success will be discussed in the section on therapy.

Vestibular anatomy

The vestibule is defined as a small cavity or space at the entrance of a canal (Fig. 4). Both Woodruff and Friedrich¹² and Friedrich¹¹ have written review articles on the anatomy of this area. The vulvar vestibule ex-

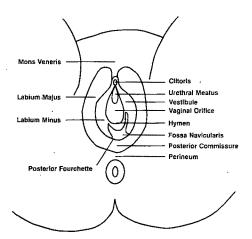

Fig. 4. External genitalia of the female.

tends laterally from the hymenal ring to a line of more keratinized skin on the labia minora, which was first described in 1882 by Hart¹⁴ and is named after him. Hart's line can be visualized in most patients with the naked eye and represents the lateral borders of the vestibule. Anteriorly, the vestibule reaches upward to the frenulum of the clitoris and posteriorly downward to the fourchette. According to Woodruff, "the vestibule represents the only portion of the female genital canal that is of endodermal origin." The urogenital. sinus of the embryo will differentiate into the adult urachus, bladder, urethra, and vestibule. It is covered with nonkeratinized squamous epithelium, an epithelial type that lies someplace between mucous membrane and skin. Within this band of tissue lie the openings of the major (Bartholin's, Skene's, and periurethral) and minor vestibular glands. As an endodermal derivative, it will be less responsive to sex steroids than its surrounding structures, which is something to consider in the treatment of vulvar vestibulitis.

Histopathology of vulvar vestibulitis

The main treatise on this subject was published in 1988. 15 Pyka et al. studied 41 patients who had a vestibulectomy with vaginal advancement performed for the treatment of vulvar vestibulitis syndrome. He demonstrated a mild-to-moderate mixed chronic inflammatory response diffusely distributed in the superficial stroma in all patients. The infiltrate was predominantly characterized by lymphocytes and plasma cells, with only small numbers of polymorphonuclear leukocytes present. When minor vestibular glands were present, they were not affected by the inflammatory cells; thus the term "vestibular adenitis" is a misnomer (Fig. 5, p. 1225).

Superficial mucus-secreting glands were identified in 66% of the patients studied. These minor vestibular glands showed some degree of squamous metaplasia in all patients, some of whom showed complete replaceAm J Obstet Gynecol

ment of the columnar epithelium forming what they called a vestibular cleft. Special histologic staining methods failed to demonstrate fungus, gram-positive bacteria, *Mycobacterium* species, spirochetes, or Donovan bodies. No evidence supported an allergic phenomenon or an immediate hypersensitivity reaction, both of which have characteristic histologic pictures. The presence of koilocytosis, histologic suggestion of human papillomavirus infection, was present in 27% of cases.

Turner and Marinoff¹⁶ demonstrated an association between human papillomavirus and the vulvar vestibulitis syndrome. Seven women with signs and symptoms of the syndrome were positive for human papillomavirus deoxyribonucleic acid using Southern blot hybridization. It was suggested that human papillomavirus was one of the causes of the syndrome.

Etiology of vulvar vestibulitis syndrome

Vulvar vestibulitis may be acute or chronic. We use 3 months of symptoms to distinguish between acute and chronic vulvar vestibulitis syndrome. Although this duration may seem arbitrary, it is useful in making therapeutic decisions. We have seen spontaneous regression of symptoms during this time period, especially if a specific cause can be found and treated. Vulvar vestibulitis of any origin invariably causes introital dyspareunia. However, if the introital dyspareunia lasts more than 3 months and becomes the primary complaint, the syndrome must then be classified as chronic.

The causes of vulvar vestibulitis are most likely multifactorial. In the acute form, the rapid relief that is seen when the presumed cause is treated suggests an etiologic relationship. In the chronic form, only an association rather than a direct cause-and-effect relationship can be implied. Many of the causes will be the same for each category, becoming chronic when the cause becomes persistent or recurrent.

Acute etiologies

Infections. Acute vestibulitis may result from any infectious process that causes vulvovaginitis. Candida, Trichomonas, and bacterial vaginosis are examples.

Irritants. Soaps, douches, and sprays are etiologic agents.¹⁷ Of special interest are those patients who have

a tendency to overcleanse with these agents, leading to irritation and symptoms.

Chemical therapeutic agents. Antiseptics, suppositories, or creams, and short-term 5-fluorouracil therapy used as treatment for condylomata acuminata play an etiologic role.

Destructive therapeutic agents. Various treatments, especially those associated with the treatment of condylomata acuminata, have led to the symptom complex. Cryosurgery, trichloroacetic acid, podophyllin, and laser treatment have been implicated.

Drug reactions. Fixed or generalized drug reactions can be seen as etiologic causes.

Chronic etiologies (Table II)

Infections

SUBCLINICAL HUMAN PAPILLOMAVIRUS. Although warty condylomata acuminata rarely cause these symptoms, subclinical human papillomavirus infection identified by a biopsy specimen or hybridization techniques is associated with the syndrome. Squamous papillae of the vulvar vestibule are seen in patients without symptoms and may be just a variation of normal anatomy. In patients with symptoms they tend to be associated with chronic irritation or human papillomavirus. The application of acetic acid and magnification, although nonspecific, will help identify the areas to be biopsied.

Growdon et al.¹⁹ reviewed 12 cases of patients with symptoms with vulvar squamous papillae. Immunoperoxidase staining revealed capsid antigen in two patients, and four of six partners had penile changes consistent with human papillomavirus. They concluded that sexually transmitted human papillomavirus was responsible for the symptoms of vulvar squamous papillomatosis. di Paola and Rueda²⁰ showed similar findings in four patients with vulvodynia and dyspareunia.

We¹⁶ presented seven women with the signs and symptoms of the syndrome who were found by deoxyribonucleic acid hybridization techniques to harbor human papillomavirus. Histologic examination was equivocal in four of seven patients. The clinical presentation before application of acetic acid was not always classic. Smooth epithelial surfaces devoid of papillations and patchy papillations, as well as the more classic florid fine papillomatosis, were seen. We proposed that human papillomavirus infection may be one of the causes of vulvodynia and the vulvar vestibulitis syndrome.

RECURRENT BACTERIAL VAGINOSIS. Alkalinity has been found to be as irritating to the vestibule as acidity. The constant bathing of the vestibule with the alkaline discharge of chronic bacterial vaginosis can lead to symptoms of vulvar vestibulitis syndrome. Treating the infection with the subsequent removal of the irritating discharge can induce amelioration of symptoms.

CHRONIC CANDIDIASIS. This term refers to chronic,

recurrent, culture-positive disease. Many patients state they have recurrent "yeast" infections when in reality they have other problems.21 Recurrent Candida vaginitis is defined by Sobel²² as the occurrence of at least four documented episodes in a 12-month period. It is often associated with chronic vaginal soreness and dyspareunia.23 We13 were unable to prove that persistent hypersensitivity to previous Candida infection was the cause of the syndrome. Also, it was neither caused by irritation nor allergic reactions to treatment vehicles. Ashman and Ott24 proposed autoimmunity as a factor in recurrent vaginal candidiasis and vulvar vestibulitis and presented an animal model. Although many patients have a history of prior "yeast" infections, the cause-and-effect relationship has not been proved.

Altered vaginal acid-base balance. As with bacterial vaginosis, other conditions that significantly alter vaginal pH can lead to chronic irritation and symptoms. Estrogen-deficient states, severe cervicitis, and the decrease in or absence of lactobacilli have been implicated.25

Miscellaneous. Other associated conditions include previous systemic chemotherapy, association with lichen sclerosus, inflammatory bowel disease, and interstitial cystitis. The mechanism of these relationships is still to be determined.

Treatment

The treatment for acute vulvar vestibulitis syndrome is medical. First, any specific infection found should receive pharmacologic treatment. Second, all therapeutic modalities, local or systemic, that may contribute to the problem should be discontinued. Finally, topical steroids should be started when the infection is controlled. Surgery is not indicated.

The treatment for chronic vulvar vestibulitis syndrome is much more complicated. Some success has been obtained when a specific etiologic condition can be identified and treated. Even here, treatment of the underlying cause does not yield a cure in many cases. Surgery has become the treatment of choice when all other modalities fail.

Subclinical human papillomavirus. With the advent of approval by the Food and Drug Administration of recombinant interferon α-2B for the treatment of condylomata acuminata, the use of this treatment for patients with subclinical human papillomavirus vulvitis and symptoms of vulvar vestibulitis syndrome became available. Hatch26 treated 22 women who had subclinical human papillomavirus infection (as proved by colposcopic examination, biopsy, and deoxyribonucleic acid hybridization) with interferon α-2B injected directly into the vulva with good results in 16 of 20 patients. He did not specifically comment on the relief of symptoms but relied on colposcopic examination and

human papillomavirus deoxyribonucleic acid probe analysis to evaluate the response. Horowitz²⁷ specifically limited his study to patients with vulvar pain characteristic of the vulvar vestibulitis syndrome and pathologic biopsy showing evidence of papillomavirus. All were at level III dyspareunia. Fifteen of 17 women responded favorably, with total absence of vulvar pain. Kent²⁸ repeated the same study in five patients, with a successful outcome in four of five patients. Of the 29 patients treated in the same fashion by the present authors, 13 had complete remission of symptoms, 3 had some improvement, and 13 had no improvement. In the same study, a cost-benefit analysis comparing interferon injections and a surgical approach showed that significant savings were realized by first treating patients with interferon rather than by immediate surgery.

Recurrent bacterial vaginosis and altered vaginal pH. The authors have identified a group of patients who have in common elevated pH of the vaginal secretions. These women complain of a copious discharge as well as the classic symptoms of vulvar vestibulitis. A distinctive observation of patients is that the symptoms worsen with an increase in the amount of the discharge. When a specific cause can be found and eliminated, there is marked improvement in their symptoms.

Recurrent bacterial vaginosis is a disease of unknown origin that results from massive overgrowth of vaginal bacterial flora, resulting in an alkaline discharge at the introitus.29 Treatment of this disorder with metronidazole or clindamycin has led to improvement in the symptoms of vulvar vestibulitis. Estrogen-deficient states may lead to secondary infection with various organisms, especially β-streptococcus. Chronic cervicitis can produce a constant discharge that tends to have an alkaline pH. Some patients have a lack of Lactobacillus not in association with bacterial vaginosis. Treating the primary condition with antibiotics, cryosurgery, or repopulating the vagina with Lactobacillus and reducing the alkalinity has been successful in improving the symptoms of vulvar vestibulitis. Care should be taken to choose a hydrogen peroxide-producing Lactobacillus product for this treatment.30

Chronic recurrent candidiasis. The association between chronic recurrent candidiasis and symptoms of the vulvar vestibulitis syndrome has been discussed. Various treatment regimens have been used with varying success. When this diagnosis can be verified, longterm treatment with oral ketoconazole has led to an improvement in the symptoms of the vulvar vestibulitis syndrome.

Surgical approach

Surgery should be reserved for patients with level II or III dyspareunia of at least 6 months' duration who

have not responded to treatment for a specific cause or for whom no cause can be established.

Woodruff et al.31 first described a procedure for the treatment of dyspareunia and vaginal outlet distortions. Eighteen of 42 patients had dyspareunia as the primary symptom; four were at level III. Dyspareunia was alleviated in all patients by a combination of surgery and, in appropriate cases, adjunct therapy for other causes. In 1983 Woodruff and Parmley¹⁰ described 14 patients with dyspareunia and minimal physical findings except for tender red papulés in the vestibule who underwent a procedure similar to that described previously. All these patients achieved major relief of symptoms. The incision extended from about 0.5 cm beneath and lateral to the urethra to the fourchette, and the vagina was mobilized to cover the defect. Between 1982 and 1984, 64 patients underwent this procedure with good results in 80% of the cases.32 It was recognized that the minor vestibular glands extend lateral to the urethra and on occasion above the urethra. Involvement of the opening of the Bartholin duct was described by Michlewitz et al.,35 who demonstrated that laser vaporization was not as effective as surgery in the treatment of these patients. This had been recognized previously by Woodruff and Friedrich.¹² When Friedrich² reviewed his patients in 1987, he found that surgery produced only a 60% cure rate. He used a similar technique as described in Woodruff and Friedrich's earlier articles. Similar results were obtained by other surgeons.34 With modification of this technique to include the periurethral areas, we and others have been able to obtain a 90% to 95% improvement rate in selected patients who meet the discussed criteria for surgery (Table III). The outer incision line extends from the periurethral glands on one side, along Hart's line, down into and including a good portion of the fourchette and back along Hart's line to the periurethral glands on the other side (Fig. 6, p. 1226). The inner incision line is behind the hymenal ring. The horseshoe-shaped tissue in between these lines is then completely excised, and the vaginal mucosa is mobilized and advanced to cover the defect. Complications include wound hematoma, partial or complete dehiscence, uneven healing requiring minor revision, and Bartholin's duct stenosis with cyst formation. Recent attempts at combining laser vaporization and vaginal advancement have not seemed to improve the results obtained with surgery alone.35

Conclusions

Too often patients with vulvar symptoms are shunted from one gynecologist to another and finally told they should seek psychiatric help. Although psychotherapy is an often neglected but very important aspect of total patient management, when there is a definite constellation of signs and symptoms, every effort should be made to elicit the cause and available treatment initiated. Vulvar vestibulitis is a syndrome with a definite set of signs and symptoms, predictable pathology, and sometimes known etiology. When a specific cause can be found, treatment yields relatively good success. Even in idiopathic cases, nonspecific treatment can sometimes be helpful. In recalcitrant cases, surgery is the only other means of obtaining relief for these patients.

Pudendal neuralgia

Maria L. C. Turner, MD, and Stanley C. Marinoff, MD, MPH

Washington, D.C.

We call attention to a group of patients with chronic vulvar burning (vulvodynia), who do not have apparent infections or easily discernible abnormal physical findings, but who on simple sensory testing have allodynia, hyperalgesia, hyperpathia, and hypoesthesia in varying permutations within the areas innervated by the pudendal nerve. We propose that pudendal neuralgia (pain along the pudendal nerve) is one of the causes of idiopathic vulvodynia. In those patients in whom a neurologic, metabolic, infectious, traumatic, or malignant cause for the neuralgia is not found, medical management with tricyclic antidepressants, antiepileptic agents, or both may prove helpful. Awareness of this entity will lead to earlier diagnosis, treatment, and reassurance of patients with chronic vulvar burning. (AM J OBSTET GYNECOL 1991;165:1233-6.)

Key words: Pudendal neuralgia, vulvodynia, allodynia, herpes simplex, tricyclic antidepressants

Interest and more directed study of the possible causes of chronic vulvar pain did not start until the early 1980s when the International Society for the

Study of Vulvar Disease set up a task force on the "burning vulva syndrome." In 1983 this task force applied the term "vulvodynia" to chronic vulvar discomfort characterized by the patient's complaint of burning, irritation, or rawness. Although there had been sporadic reports in the literature and short entries in text-books on some pathologic causes of chronic vulvar burning and discomfort, the psychosomatic origins of these complaints received as much if not more atten-

1234 Turner and Marinoff October 1991
Am J Obstet Gynecol

tion.^{2,3} In a state-of-the-art paper, McKay⁴ summarized the currently known causes or conditions associated with vulvodynia: vulvar dermatoses, recurrent candidiasis, vulvar vestibulitis, and a group labeled "essential vulvodynia." This last group of patients said to have "essential vulvodynia," who complain of constant or nearly constant vulvar burning and have a paucity of physical findings, will be the focus of this article. We propose that most of these patients suffer from pudendal neuralgia. The possible causes of pudendal neuralgia are varied, and we include citations from the literature and the results of our investigations.

Definition and history

As an entity, pudendal neuralgia has not merited much attention in textbooks of neurology. Wilson⁵ described this condition as characterized by "mostly vague but sometimes well-defined pains, referred to perineum, scrotum, testis, penis, and spermatic cord...often very severe and at times paroxysmal." He described extreme sensitivity to touch such that even light pressure became intolerable. Men appeared to be more commonly afflicted, although women could be similarly afflicted in analogous locations. In his experience, the majority of such patients were neurotic. Earlier Zuelzer6 called attention to the fact that irritation of the pudendal nerve could be mistaken for cystitis due to the complaints of frequency and dysuria. However, the accompanying increase in skin sensitivity in the perineum made him recognize these cases as pudendal neuralgia.

Anatomy

The perineum has an overlapping nerve supply⁷ with some branches from the iliohypogastric nerve (T-12 and L-1), the ilioinguinal nerve (L-1), and the genitofemoral nerve (L-1 and L-2). However, the vast majority of its nerve supply (sensory, motor, and autonomic) is drawn from the pudendal nerve (S-2, S-3, and S-4), which eventually divides into the perineal nerve, the dorsal nerve of the penis or clitoris, and the inferior hemorrhoidal nerve. Using a needle for testing, Zuelzer was able to delineate a rhomboidal area of increased sensitivity around the perineum. The anterior border was a few centimeters above the symphysis pubis, the posterior border was behind the anus, and the upper, inner thighs formed the lateral limits (Fig. 1, p. 1226).

Symptoms

Almost all patients complain of an unprovoked, persistent, superficial, burning sensation that is frequently accompanied by a deep, aching component. Some patients also experience rare, paroxysmal lancinating or stabbing pains over a larger area. Patients who are less severely involved initially complain of an itch-burn sen-

sation or a feeling of rawness. Some patients perceive burning pain when the vulvae are lightly stroked with a cotton wisp (allodynia). This corresponds with their frequent observations that light touch, clothing, water, and even the motion of their pubic hairs lead to burning pain. It follows that these patients complain of dyspareunia not only on penile penetration but also during and after intercourse. Patients who are more severely affected are unable to have intercourse. It is not unusual for patients to report rare, unexplained, symptom-free periods lasting for days to weeks.

The above set of symptoms are felt over various areas supplied by the branches of the pudendal nerve, unilaterally, bilaterally, or in an asymmetric fashion. The following structures are seen to be involved singly or in various combinations: cutaneous surfaces of the labia majora and minora, clitoris, urethral meatus, vulvar vestibule, anus, perineum, and perianal skin.

Involvement of the urethral meatus leads to "cystitis-like" symptoms of frequency and dysuria in the presence of negative cultures. "Sciatica-like" pains are sometimes reported.

Physical findings

There is usually a paucity of physical findings. The vulvar lining may have variable textures. Some appear to have normal markings, whereas others seem smooth and nearly sclerotic. Some labia appear somewhat hypertrophic and cobblestoned. There is generally no evidence of infection, abnormal wet smears, or pH changes. This may explain why women who have the above constellation of symptoms are frequently labeled as hysterical, neurotic, or malingering.

Focal vestibular erythema with or without tenderness is sometimes seen. The relationship of these findings to this entity is not clear.

Positive findings that may be helpful include the presence of thickened surgical scars at the painful site, the presence of a palpable tumor, and evidence of genital herpes. It is sometimes helpful to examine the patient at the height of the symptoms, because this might be an opportune time to see herpetic vesicles. This has been our experience innumerable times.

Sensory testing with a cotton wisp and a sharp pin may elicit any combination of the following responses:

Allodynia: Pain caused by a stimulus that does not normally provoke pain.

Hyperalgesia: An increased response to a stimulus that is normally painful. An example is severe sharp pain provoked by a light pin-prick.

Hyperpathia: A painful syndrome characterized by increased reaction to a stimulus, especially a repetitive stimulus. Delay in sensation, radiating sensation, and af-

ter sensation are other qualities that define this condition.

Hypoesthesia: Diminished sensitivity to sensory stimulation.

Diagnostic tests

Among useful diagnostic assays are the Tzanck smear and culture for herpes simplex from suspicious lesions anywhere along the lower genital tract. Determination of evoked potentials can also be obtained, but this is not an easy test to perform in this area, and norms are not clearly established. Medical examination and blood chemistries should be obtained when indicated to rule out metabolic causes of neuropathy. Radiographic studies of the lumbosacral spine may be performed to rule out disk problems, arthritis, or space-occupying lesion.

Etiology

Pudendal neuralgia has been reported after surgical and nonsurgical trauma,8 sports trauma such as "unicyclist's sciatica,"9 and from horseback riding.10 It has been seen in association with a solitary neurofibroma¹¹ and in one of our patients with multiple sclerosis. The most common association, as seen in our practice and as reported in the literature, is with herpes simplex.12, 13

Treatment

Depending on the severity of the problem, a combination of several modalities may be necessary.

- 1. Nonsteroidal antiinflammatory agents, although frequently used, have not proved helpful in most cases.
- 2. In mild cases, a tricyclic antidepressant such as amitriptyline^{14, 15} at a dose of 10 to 75 mg before bedtime is helpful. It may take 2 to 3 weeks to reach efficacy, and its use may be limited by side effects that include sedation, excitation, and anticholinergic effects such as dry eyes and mouth, weight gain, and photosensitivity. Imipramine and other tricyclics may be substituted for amitriptyline until a tolerable one is found. The analgesic effects occur at doses much lower than those required for antidepressant effects.
- 3. Anticonvulsants, such as phenytoin and carbamazepine,16 have been used successfully in postherpes zoster neuralgia. Carbamazepine may be started at a dose of 100 mg, increased by increments of 100 mg every 2 days until a daily dose of 600 mg is reached unless pain relief occurs at a lower dose. It should be administered every 8 hours to maintain therapeutic blood levels. Because of hematologic, dermatologic, and hepatic toxicities, close monitoring is necessary. Phenytoin

- is given at the rate of 300 to 400 mg a day in two divided doses to attain adequate serum levels. If no relief of pain is achieved in 3 weeks, the drug should be discontinued, because higher doses lead to toxicity.
- 4. Systemic acyclovir, 200 mg three times daily, for long-term prophylaxis in proven cases of recurrent genital herpes simplex is helpful to prevent the acute pain associated with recurrence. Alone it does not alleviate the chronic burning component.
- 5. Surgical procedures, such as nerve sections, excision of scar tissue, sympathectomy by way of dorsal root entry zone, may be tried in recalcitrant cases.
- 6. Miscellaneous therapies, such as acupuncture, transcutaneous electrical stimulation, topical anesthetics, regional blocks, and capsaicin, have been tried with inconsistent results. Although capsaicin is considered helpful for postherpes zoster neuralgia, the few patients we have treated could not bear the vulvar stinging from its use.
- 7. Psychotherapy is an often neglected but very important aspect of total patient management. Studies have shown a very high incidence of depression in patients with long-term pain of more than 3 months' duration.

Conclusion

We have attempted to call the attention of practicing gynecologists, dermatologists, and other physicians who treat women with vulvar problems to another possible cause of chronic vulvar burning. It is particularly useful to consider this diagnosis when there are few physical findings. A screening sensory evaluation will quickly determine whether pudendal neuralgia is a serious consideration and whether referral to a neurologist might be indicated. Our current experience with therapy has not been encouraging except for the milder cases or those that are not chronic. More research is necessary to determine optimal treatment.

Toxic shock syndrome: An update

Arthur L. Reingold, MD

Berkeley, California

Since late 1979 to early 1980, when toxic shock syndrome achieved notoriety, a substantial body of data has demonstrated that vaginal Staphylococcus aureus infections, particularly those occurring during menstruation, account for most cases of toxic shock syndrome in women of reproductive age. Among those patients with onset during menstruation, tampon use has been identified as the most important risk factor. Although menstrually associated cases have been observed among users of all brands and styles of tampons, the use of selected "super absorbent" brands and styles has been associated with an increased risk of toxic shock syndrome. Although the tampon characteristics responsible for the associated risk of toxic shock syndrome remain poorly understood, both absorbency and chemical composition appear to be important variables in this relationship. In response to studies demonstrating this relationship and legal pressures, tampon manufacturers have removed chemical constituents previously used to enhance absorbency, such as polyester foam, carboxymethylcellulose, and polyacrylate rayon, and have markedly reduced tampon absorbency. Coinciding with these changes, the reported number of menstrually related cases of toxic shock syndrome has dropped substantially, although they continue to account for 50% to 70% of all cases of toxic shock syndrome in women of reproductive age. (AM J OBSTET GYNECOL 1991;165:1236-9.)

Key words: Toxic shock syndrome, tampons, Staphylococcus aureus

Toxic shock syndrome (TSS) is a severe, potentially life-threatening systemic illness resulting from infection with toxin-producing strains of Staphylococcus aureus at any body site. TSS achieved notoriety in 1980, when large numbers of cases among young, previously healthy women who were menstruating began to be noticed by clinicians and public health officials. Since then, much has been learned about the clinical and epidemiologic aspects of TSS, and in vivo and in vitro laboratory studies have elucidated the bacterial prod**Table I.** Simplified case definition of TSS

Fever: Temperature ≥38.9 °C (102° F) Rash: Diffuse macular erythroderma Hypotension: Systolic blood pressure <90 mm Hg or orthostatic changes in blood pressure Desquamation 1-2 wk after onset of illness Evidence of involvement of ≥3 body systems (gastrointestinal, muscular, mucous membrane, renal, hepatic, hematologic, and central nervous system) No evidence of another cause for the illness

ucts and the elements of the host response that combine to produce the pathophysiologic changes seen. Based on the results of the epidemiologic and laboratory studies, as well as on legal and financial considerations, the manufacturers of tampons have dramatically altered the products they market. The incidence of tampon-

Table II. Complications of TSS

associated TSS has declined substantially since 1980 at least partially because of such changes.

Clinical features

For epidemiologic purposes, a strict case definition was developed for TSS in 1980,1 a simplified version of which is presented in Table I. Although epidemiologists and (to an even greater extent) lawyers have relied on this case definition to divide the world neatly into those patients who do and those who do not have TSS, most clinicians recognize that many patients with what undoubtedly are milder cases of TSS do not fulfill all the listed criteria. Although virtually all patients with TSS severe enough to meet this case definition require hospitalization at least for a few days, it is likely that many milder cases of TSS are treated on an outpatient basis or resolve spontaneously. Although unproved, it seems reasonable to suspect that in mild cases the amount of toxin released is reduced or that such cases occur in persons who are partially immune because of prior exposure to the responsible toxin. It is also possible that variation in the severity of cases is due to differences in the infecting S. aureus strains, either in the amounts or the type of toxin being produced and released.

Currently TSS meeting the strict case criteria has a case-fatality rate of approximately 2%, although fatality rates of 4% to 5% were noted in the early 1980s. Although a wide range of complications has been observed in severe cases of TSS (Table II), adult respiratory distress syndrome, acute renal failure, and disseminated intravascular coagulation have been the most troublesome. A number of characteristic laboratory changes also are seen in TSS (Table III), although none is unique to TSS.

The treatment of TSS remains largely supportive. Initially the most important are adequate drainage of any infected site to further minimize uptake of toxin; replenishment of intravascular volume with sometimes prodigious amounts of replacement fluids; support of blood pressure with pressor agents when required; and treatment of life-threatening complications such as respiratory or renal failure. Treatment with an antimicrobial agent effective against S. aureus is also a routine part of the management of TSS, although it may be

Table III. Distinctive laboratory changes in TSS

Immature and mature neutrophils >90% of white blood cell differential Pvuria Hypocalcemia Hypophosphatemia Hypoferrinemia Hypoproteinemia/hypoalbuminemia Azotemia Increased liver enzyme Increased creatine phosphokinase Isolation of S. aureus from infected site

more important in preventing recurrences than in improving outcome of the acute illness. High-dose corticosteroids, although reported to be of some benefit in severe TSS, have not been well studied. Treatment with human immune serum globulin, which can be expected to contain antibodies to the toxin responsible for most cases of TSS, might theoretically be of benefit in treating TSS by binding circulating toxin, although there is no clinical experience with such therapy.

Descriptive epidemiology

Since 1980, there has been a dramatic decline in the number of cases of TSS reported through the national passive surveillance system (Fig. 1).2 Some of the increase in TSS cases seen in 1980 and some of the subsequent decrease are undoubtedly due to artifacts produced by changes in disease recognition and reporting. However, it is interesting to note that reporting of nonmenstrual cases of TSS does not appear to have been affected by such artifacts, with a relatively constant number of such cases reported annually for the past 10 years. Furthermore, evidence from other studies^{3, 4} in which artifacts were eliminated show similar trends in the incidence of menstrual TSS. These trends are quite consistent with and largely explained by documented changes in the chemical composition, absorbency, and usage patterns of tampons during the same time period.

The current distribution of TSS cases is best reflected in data collected using active, hospital-based surveillance in five states and one large county in 1986 and 1987.5 Of the 179 cases of TSS detected by this active surveillance system, 85% were in girls and women and 15% were in boys and men (Table IV). Of the 152 cases in girls and women, only 55% had onset during menstruation, whereas another 10% were associated with use of barrier contraception and 7% occurred in postpartum women. The remaining cases in men and women were due to S. aureus infections at a wide array of body sites. Data from the same study, as well as data from a chart review study designed to find all cases of TSS in men and women 15 to 34 years of age whether

diagnosed or not,⁴ document that young women (15 to 19 years) are at greater risk than older women of menstrual age and that white women are at greater risk than nonwhite women. Previously observed variations in the incidence of menstrual TSS in different regions of the United States appear to have largely disappeared, and the current incidence of menstrual TSS in all regions from which there are appropriate data is in the range of 1 to 3/100,000.

Risk factors for TSS

Numerous studies consistently and convincingly have shown that tampon use is the major risk factor for TSS occurring during menstruation. Even in 1986 to 1987, after enormous changes in the chemical composition of tampons and marked reductions in their absorbency, an elevated risk of menstrual TSS among tampon users was redemonstrated. Epidemiologic studies from the early and mid-1980s demonstrated that the risk of menstrual TSS varied directly with the absorbency of the tampon used and suggested that the chemical com-

position of the tampon also was important in determining the risk of TSS.⁷⁻⁹ In vitro studies confirm that the chemical composition of a tampon can markedly affect the production of the staphylococcal toxin thought to be involved in more than 90% of all menstrual cases of TSS.^{10, 11} Among nonmenstrual cases of TSS associated with *S. aureus* infections of the vagina, the use of barrier contraception (diaphragms and contraceptive sponges) is the only known risk factor.¹²

Microbial factors and pathogens

As noted above, TSS can be caused by infections at any body site with strains of *S. aureus* that produce certain exoprotein toxins. The overwhelming majority (>90%) of menstrual TSS cases are caused by *S. aureus* strains that make TSS toxin-1 (TSST-1), the toxin most clearly identified with TSS.¹³ The ability of purified TSST-1 to produce a similar illness in rabbits and the ability of antibody to TSST-1 to block such illness demonstrate convincingly that TSST-1 can produce TSS. However, many (>30%) of the *S. aureus* strains recov-

ered from patients with nonmenstrual TSS do not make TSST-1, and it appears that staphylococcal enterotoxins, particularly enterotoxins B and C, can produce a clinically indistinguishable syndrome.

TSST-1 and the staphylococcal enterotoxins now appear to be extremely interesting molecules that can act as "super antigens," having profound effects on the human immune system and producing an outpouring of various endogenous factors, such as the interleukins and tumor necrosis factor.14 Furthermore, the production of TSST-1 by S. aureus has now been shown to be markedly dependent on the level of ambient oxygen, glucose, magnesium, and other factors, some of which can be introduced into or removed from the vagina by the presence of tampons of various compositions. Thus tampons may increase the risk of menstrual TSS by affecting the level of various factors that in turn affect the production of TSST-1.

Host factors

The presence of toxin-producing S. aureus at a body site, although necessary for TSS to develop, is clearly not sufficient. Numerous studies have demonstrated that nasal and vaginal colonization with TSST-1-producing S. aureus is fairly common, whereas TSS is quite rare. Thus it is clear that other conditions must be met for TSS to develop. One factor likely to be important in determining whether TSS will develop is the presence or absence of preexisting antibody to TSST-1. Although the source remains obscure, it is clear that antibodies to TSST-1 are acquired during the first 15 to 20 years of life, such that by age 20 to 25 years, more than 90% of men and women have detectable anti-TSST-1 antibodies. If, as is believed, such antibodies protect against the development of TSS, then only a small proportion of people are susceptible to developing TSS when infected with a TSST-1-producing strain of S. aureus. However, even after taking such serosusceptibility into account, as well as what proportion of menstruating women use tampons and what proportion are infected with a TSST-1-producing strain of S. aureus, the observed number of menstrual cases of TSS is much lower than would be predicted. Therefore other currently unknown host factors and vaginal conditions must also be important in determining which serosusceptible, menstruating women who are infected with such a strain will develop TSS.

Prevention

Despite the dramatic changes in tampon formulation since the early 1980s and the observed sharp decline in menstrual TSS, the risk of menstrual TSS still appears to be elevated among users of many, if not all, currently available brands and styles of tampons.7 If a

woman wishes to reduce her already very small risk of developing menstrual TSS, she can do so by using napkins or pads instead of tampons. Because this choice will be unacceptable to many women, those women who continue to use tampons can be advised to use the lowest absorbency tampons compatible with their needs and to alternate tampons with pads or napkins, perhaps using the latter at night. Although frequent changing of tampons has never been demonstrated to reduce the risk of menstrual TSS, it is reasonable to suggest that an individual tampon not be left in place too long. Women who use tampons should read the warning label or package insert concerning TSS that is now found on or in all tampon packages. If symptoms compatible with TSS develop, a woman should remove her tampon and seek prompt medical attention.

Nonbarrier contraceptives and vaginitis and vaginosis

Subir Roy, MD

Los Angeles, California

Within the limitations of the available data, it has been reported that oral contraceptive use versus other contraceptive methods is associated with a greater or similar frequency of candidiasis, increased numbers of anaerobic microorganisms, an increased or similar frequency of *Chlamydia trachomatis*, and a reduced frequency of bacterial vaginosis and trichomoniasis. The impact of contraceptive steroids on cellular and humoral immunologic factors may explain these observations. Intrauterine contraceptive device use is reported to be associated with an increased rate of bacterial vaginosis and anaerobic organism recovery from the vagina regardless of symptoms. Patients having a contraceptive vaginal ring were found to have the same number and types of vaginal organisms as oral contraceptive users. Levonorgestrel-releasing subdermal implant (Norplant, Wyeth-Ayerst, Philadelphia, Pa.) users have been reported to have approximately half the rate of vaginitis and vaginosis compared with that of Copper T-200 intrauterine device users. (AM J OBSTET GYNECOL 1991;165:1240-4.)

Key words: Contraceptives, oral contraceptives, intrauterine devices, vaginitis, vaginosis, candidiasis, *Chlamydia trachomatis*, trichomoniasis

The ideal manner to study the relationship between contraceptive use and the development of vaginitis and vaginosis would require a prospective, randomized study adjusted for age, parity, sexual activity, smoking, and other potentially confounding factors. Studies incorporating all these aspects have not been performed. Typical reports, even if prospective, study nonrandomized allocation of patients to contraceptive methods and are limited in scope. Usually patients who complain of vaginitis or vaginosis have been investigated to assess their use of contraceptives. Case-control studies such as these, although easier to perform than cohort studies, have their usual biases and limitations. Thus only the number of patients with these complaints who seek medical attention (the numerator) is available, and we do not know the number of patients who use the various methods of contraception (the denominator). This type of information does not permit the calculation of predictive value (or likelihood) of the development of vaginitis and vaginosis by use of each method of contraception. Thus we can only report the frequency with which each method of contraception is used by the type of vaginitis and vaginosis being considered.

Material and methods

A literature search was performed. Studies have been included in this review that appeared to provide useful information regarding the association of vaginitis and vaginosis with the use of oral contraceptives (OCs), intrauterine devices (IUDs), contraceptive vaginal ring (a

vaginal method but not a barrier method), and Nor-plant.

Results

Osborne et al.1 examined the relationship between vaginitis and sexually transmitted organisms in sexually active women. Symptomatic women (n = 253) and a control population of asymptomatic women (n = 130)were identified and examined. Each group used the same proportion of birth control methods (OCs, 64% and 72%; IUDs, 7% and 6%; barrier contraception, 11% and 12%; and other contraception, 18% and 10%, respectively). Therefore the method of birth control was ignored in the remainder of the study. When the potentially sexually transmitted disease organisms recovered from the symptomatic and asymptomatic groups were examined (Table I), herpes simplex, Neisseria gonorrhoeae, Gardnerella vaginalis (a marker for bacterial vaginosis), Trichomonas vaginalis, and yeasts were significantly more prevalent in the symptomatic than in the asymptomatic group. Conversely, as one would expect, the asymptomatic group was more likely to have none of the above. However, the incidence of Chlamydia trachomatis was not significantly different between these two groups, nor was the incidence of genital mycoplasmas or group B streptococcus. Thus from this relatively recent study published in 1982, it would appear that vaginitis is not associated with the method of birth control.

However, if we review earlier literature on candidiasis (Table II), a prevalence study by Jensen et al.² published in 1970 found a 15% rate of candidiasis in OC users compared with a 5% rate in non-OC users—a significant difference. A prevalence study by Catterall³ in 1971 reported that 99 of 200 patients with vaginal

candidiasis used birth control pills. A prevalence study by Bramley and Kinghorn⁴ in 1979 reported that 68% of OC users versus only 32% of users of other methods had yeast infection, a statistically significant increase. These three studies suggest an association between yeast infections and OC use. However, not all data support this association.

For example, a prevalence study by Davidson and Oates⁵ in 1985 examined the occurrence of yeast in the vaginas of unselected women. When subjects are chosen in this manner, one is impressed by the similarity in the percentage of yeast infections, regardless of the use of OCs, IUDs, other methods, or no method. Therefore the conclusion differs depending on the sample and how it is obtained.

It has been postulated that the mechanism by which yeast cells proliferate is linked with the immunologic competency of the host. Kalo-Klein and Witkin6 reported on the relationship of the menstrual cycle to lymphocyte proliferation and serum-induced germination of Candida. At midcycle, with estrogen predominance and a virtual absence of progesterone, they found the greatest proliferation of lymphocytes and the greatest percentage of ungerminated Candida. The next part of their study, which examined the effect of birth control pills, found that the percentage of ungerminated Candida tended to be higher overall in those patients taking birth control pills. This study suggests a mechanism by which Candida and birth control pills may be linked.

One of the earliest reports of C. trachomatis (Table II) by Washington et al.7 in 1985 reviewed 14 epidemiologic studies and found that in 12 studies the prevalence of C. trachomatis in the endocervix of OC users was three times that of nonusers of OCs. In a prevalence study by Handsfield et al.8 in 1986, the rates of Chlamydia were similar for all methods of contraception except for other or barrier methods, which had the lowest rate (3.5%). When they applied a stepwise multiple logistic model regression curve to use of no contraception or a nonbarrier method (i.e., the OC and IUD groups), they found a significantly increased odds ratio for those

persons. Therefore this study reports an increased prevalence of *C. trachomatis* not only in the OC group but also in the IUD group. In a prospective study conducted over a 2-year period, Avonts et al.⁹ showed that the percentage cumulative chance of infection with *C. trachomatis* was significantly greater in the OC group (15%) versus the IUD group (4%) at the end of this time period.

This same cohort study by Avonts et al. reported on the occurrence of bacterial vaginosis (Table II). At the end of 2 years, 15% of OC users and 45% of IUD users had bacterial vaginosis, a significant difference. They concluded that symptomatic bacterial vaginosis was associated with IUD use, but asymptomatic bacterial vaginosis was associated with promiscuity. At 6 months, more persons in the IUD group than in the OC group had "pelvic inflammatory disease—like symptoms," but by 24 months there was no statistically significant difference between these two groups.

In 1979 Bramley and Kinghorn also reported on the decreased prevalence of *T. vaginalis* in OC users (37%) compared with users of other methods of contraception (63%) (Table II). In 1980 Fouts and Krauss dexamined clinical epidemiologic variables in women with and without vaginitis caused by *T. vaginalis*. Forty-four percent of the OC group had trichomoniasis, whereas 56% did not. Thirty-four percent of patients using no method of contraception also had trichomoniasis.

Obviously there are other organisms in the vagina, and Haukkamaa et al. "(Table III) compared the recovery of isolates from the endocervix of barrier method, OC, and IUD users. Seven of the 30 persons had only a single isolate recovered, whereas most had multiple isolates. In comparing the different methods, IUD users had significantly more aerobic colonies than barrier method users; also, both OC and IUD users had significantly greater numbers of anaerobic isolates than did users of barrier methods. Fundamentally, these data suggest that both the OC and the IUD users harbor more aerobic and nonaerobic organisms than users of barrier methods at the level of endocervix.

Kivijarvi et al.¹² studied three groups of persons (Table IV). Group I was IUD users, most of them Copper-7 or T users, with symptoms of vaginitis; group II was IUD users without symptoms. Both groups had these devices removed. Group III were non-IUD users without symptoms who were going to have them inserted at the time of this visit. Anaerobic rods were more prevalent in those IUD users with symptoms compared with those without symptoms when cultures were taken from the posterior fornix. However, a large number of organisms was found in all of these groups.

After cultures were taken, the cervix was then washed with saline solution, the speculum was removed and another put in, and the IUD was removed in a sterile fashion. An "endocyte," an instrument from France, was used to obtain a culture from the endometrium. There were more *G. vaginalis* in those women with

NOR, Norplant; TCu, Copper T.

symptoms compared with those without symptoms. Anaerobic rods and cocci were more prevalent in those patients with symptoms than without symptoms. Multiple organisms were recovered from the endometrium from several individuals not using an IUD and without symptoms. There were percentages of greater recovery of all organisms except lactobacilli from the IUDs of those with symptoms than without, although these differences did not reach statistical significance.

A recent study by Roy et al. 13 compared the recovery of organisms from users of the contraceptive vaginal ring and women taking OCs. The contraceptive vaginal ring is a silicone rubber device in the shape of a donut, with the active ingredient in the middle portion of a three-layer shell design. This vaginal ring releases levonorgestrel and estradiol. The comparison group consisted of individuals taking OCs containing levonorgestrel and ethinyl estradiol. Cultures were obtained from the posterior fornix before randomization to this therapy and then at the end of 6 months of therapy. In Table V¹³ the numbers of subjects are presented in whom there was a 10¹ order increase or reduction in cultures, no change, those who did not have a positive culture at the beginning but had it at the end, those who had it at the beginning, lost it at the end, and then those in whom no change occurred, or positive culture was never present. No demonstrable change in the pattern of recovery for these types of organisms occurred in those patients who used the vaginal ring or OCs.

Norplant, a subdermal method of birth control, releases levonorgestrel from six Silastic capsules, each 3 cm in length. They are inserted subcutaneously in the medial aspect of the upper arm and release a small amount of levonorgestrel into the circulation. This method is being used worldwide presently and has recently been approved in the United States by the Food and Drug Administration. Some data are available with respect to the issue at hand; namely, cervical problems, vaginitis, leukorrhea, vulvitis, and other vaginal or vulvar symptoms. In 1983 Sivin¹⁴ reported on 1, 2, and 3 years of use of Norplant, a 5-year method, and compared it with the Copper-T IUD, which at that time was a 3-year method (Table VI). Norplant users had approximately one third fewer complaints compared with Copper-T users. When these individuals were actually examined, Norplant users had about 40% to 50% of the vaginal or vulvar complaints compared with IUD control subjects.

Comment

The studies that would provide answers for the purpose of this review are not available. However, those studies that are available suggest that OC use probably does not change the risk of candidiasis, may increase the risk of C. trachomatis and in fact appears to reduce the risk of bacterial vaginosis and trichomoniasis compared with other nonbarrier methods of birth control. IUD use does not change the risk of candidiasis or C. trachomatis; indeed, the incidence of the latter may be lower than in the OC users. However, the rate of bacterial vaginosis may be increased compared with OC users. Interestingly, the link between IUD use and "pelvic inflammatory disease-like symptoms" suggested by Avonts et al.9 appears to be related to promiscuity. This confirms the observations with IUD use: namely, that there may be a risk of infection of the upper genital tract immediately after IUD insertion; thereafter, the risk is the same as acquiring a sexually transmitted disease.15 The report by Kivijarvi et al.12

supports the concept of Hemsell et al.¹⁶ that even women without symptoms may harbor microorganisms in the upper genital tract without evidence of disease. The contraceptive vaginal ring and Norplant appear not to be related to any particular vaginitidies. In conclusion, given the constraints of the published studies, there does not appear to be any direct association between any of these methods of contraception and the occurrence of the various vaginitidies.

Cytolytic vaginosis

Leonard J. Cibley, MD, and Laurence J. Cibley, MD

Boston, Massachusetts

Cytolytic vaginosis, a not uncommon condition, is frequently misdiagnosed because it is confused with *Candida*. Many practitioners rely on their clinical judgment alone rather than the use of high-quality microscopes and the results of a wet smear. Compounding the problem of misdiagnosis is that patients assume that their symptoms are caused by a yeast infection, which results in telephone requests for medication from their physicians instead of an office consultation. Cytolytic vaginosis is characterized by pruritus, dyspareunia, vulvar dysuria, and cyclical increase in symptoms more pronounced during the luteal phase. Diagnostic criteria include a high risk of suspicion; the absence of *Trichomonas, Gardnerella*, or *Candida* on wet smear; an increased number of lactobacilli; a paucity of white blood cells; evidence of cytolysis; and the presence of discharge; and a pH between 3.5 and 4.5. Treatment entails use of sodium bicarbonate douches. (AM J OBSTET GYNECOL 1991;165:1245-9.)

Key words: Vaginosis, vaginitis, Candida, Lactobacillus

Cytolytic vaginosis is a newly coined name for an old ailment, Döderlein's cytolysis, which is quite common. In our experience, *Lactobacillus* overgrowth and candidiasis are frequently confused, and many patients referred for treatment of "chronic yeast infections" are singularly free of *Candida*.

The fault lies with the clinical practice of relying on color and physical characteristics of a vaginal discharge to make a diagnosis. The errors are further perpetuated by the so-called "easy diagnosis of vaginitis" charts that use color and consistency of discharge, as well as symptomatology as diagnostic criteria. Too many of us fervently believe that we can accurately diagnose a case of "Monilia" and that "after 20 years in practice, I do not need a microscope to diagnose an ailment that I have seen a thousand times." In our practice, if we are unable to make a diagnosis, we instruct the patient to refrain from sexual relations and not to use vaginal medications or douches. She is further instructed to return to the office in 48 to 72 hours. Using this protocol, we are almost always able to make an accurate diagnosis.

We challenged the accuracy of the "eyeball" diagnosis at the 1985 national meeting of the American College of Obstetricians and Gynecologists.' In a scientific exhibit, after viewing a series of slides, participants were asked to register a diagnosis based solely on color, consistency, and physical characteristics. The average score of those physicians was 30%.

Often a patient manipulates her physician into pro-

viding medication for a "yeast infection" that was never clinically examined, but, rather, diagnosed on the telephone. "The telephone," as stated by Friedrich, "is neither a diagnostic nor a therapeutic tool and the temptation to use it as such should be resisted."2 Too many patients and far too many physicians believe that if you have ever had or been told that you had a yeast infection, then any further vaginal discharge, accompanied by pruritus, automatically should be treated as Candida. The recent Food and Drug Administration decision to allow the over-the-counter purchase of clotrimazole and miconazole will undoubtedly add to the tremendous therapeutic confusion and encourage the overdiagnosis and incorrect treatment of so-called Candida. The concept of self-treatment will also lead to failure to diagnose and treat the more dangerous sexually transmitted diseases. Blind diagnosis compounded by conjectural pharmacology is akin to playing vaginal roulette.3

It is imperative to point out that even if a discharge is white, cheesy, and found to test in the pH range of 3.5 to 5.0, it still may not be *Candida*. Many women, discouraged by the failure of traditional medical treatment, follow a cult-like, self-help group which employs garlic-impregnated tampons, myrrh pastes, and acupuncture. They also use herbal drugs, yogurt, and massage in an attempt to alleviate debilitating symptoms. The standard dictum of "when in doubt, douche with vinegar" has become widely regarded as a cure-all. All of these exercises are futilely carried out to restore the *Lactobacillus* as the defender of vaginal health.

For nearly a century, physicians and microbiologists have championed the Döderlein's bacillus as the savior of women. Cruickshank and Sharman⁴ described three grades of vaginal health that were dependent on

the number of Döderlein's bacilli in the vagina. Fifty years ago, Weinstein reported that there seemed to be no correlation between vaginal pathology and the presence or absence of the Döderlein organism, with the exception of the gonococcus and the trichomonad, in which case, Döderlein's organism was never demonstrated. The earlier philosophy of correlating vaginal health with the numbers of lactobacilli is no longer a viable hypothesis. Sobel, as well as Larsen and Galask, concur with Weinstein's original findings.

While the authors recognize that chronic candidiasis is a definite entity, the majority of patients referred to our practice are found to be suffering from the entity previously described as Döderlein's cytolysis. From its inception, cytology has recognized the phenomenon of cytolysis. Bibbo⁸ reported cytolysis as a common finding on Papanicolaou smears and suggested distilled water douches to raise the pH. She did not, however, describe the condition as a clinical entity. Inasmuch as only a few species of lactobacilli are, in fact, Döderlein's bacilli, it became apparent to the authors that the term Döderlein's cytolysis is a misnomer and that a far more appropriate description is cytolytic vaginosis.⁹

The woman with a chronic, uncured vaginitis is frequently advised to seek psychiatric counseling, or even worse, to find the "ultimate cure" by having her cervix and uterus removed. Although Döderlein's bacillus was first described in 1892,10 we now know that the organism bearing Döderlein's name is not a uniform entity but is equally applied to the Lactobacillus and other rods.11 The Lactobacillus is a pleomorphic, grampositive, aerobic or a facultative anaerobic, non-sporeforming organism. As many as 80 different species have been described. Numerous investigators have observed that the Lactobacillus is found in normal vaginal secretions and is associated with a high degree of acidity. Rakoff and associates questioned whether the lactic acid in the vagina resulted from conversion of carbohydrates by certain bacteria, that is, the Döderlein bacteria.12 They further asked whether there was enzymatic fermentation of carbohydrates to lactic acid by other mechanisms irrespective of the Lactobacillus. 12

Many early studies have confirmed that the vagina is rich in glycogen; in fact, it is second only to the liver in total glycogen concentration. The question of whether the *Lactobacillus* is capable of fermenting glycogen to lactic acid is of continuing debate. Cruickshank and Sharman, as well as Wylie and Henderson, shave demonstrated that some strains of *Lactobacillus* are capable of directly fermenting glycogen, and that the "vaginal acidity is brought about, in part, at least, by the vaginal *Lactobacillus*." They further demonstrated that the majority of lactobacilli strains are unable to

ferment glycogen directly but are capable of fermenting glucose. ¹³ Stewart-Tull¹⁴ hypothesized that the "vaginal *Lactobacillus* lacked either phosphorylase or glucosidase" and believed that high acidity in the vagina was caused by the breakdown of glycogen to free glucose by muscle phosphorylase and glucosidase. The free glucose can then, in turn, be fermented by the *Lactobacillus*.

Many species of lactobacilli ferment glucose predominantly to lactic acid with only a trace amount of other products by homolactic fermentation, whereas others are heterolactic fermenters that produce a mixture in which half of the glucose is converted to lactic acid, with the remainder forming a carbon dioxide, alcohol, formic acid, or acetic acid.¹⁵

The normal flora of the vagina exists in an everchanging arena of physiologic checks and balances. The inhibition of the growth of one species of bacteria by liberation of H₂O₂ by another species is a well-known mechanism of bacterial control.16 Lactobacilli and other lactic acid producers lack heme and are incapable of using the cytochrome system to form H2O. Lactobacilli use flavoproteins which convert O2 to H2O. Flavoprotein enzymatic action, combined with the lack of the heme protein, catalase, produces large amounts of H₂O₂. This excess formation may kill or inhibit other bacteria, especially those that lack or have suboptimal H₂O₂ scavenging enzymes, that is, catalase peroxidase. The bactericidal property of H2O2 is markedly enhanced by the enzyme peroxidase in the presence of a halide ion. The peroxidase enzymes that function in this manner are found in milk and saliva, neutrophils, monocytes, and eosinophils, and in genital tract secretions, including cervical mucus.17

The concept of cytolytic vaginosis has not been adequately explored and continues to raise questions. If this is a pathologic entity, it is natural to question why more women are not afflicted with this overgrowth of lactobacilli. The answer may very well lie in the symbiotic relationship among various naturally occurring bacterial flora and the differences in their fermentation by-products caused by the differentiation of species of *Lactobacillus*. To date, intensive bacteriologic studies, including quantitative studies of vaginal flora, have not been helpful in clarifying the issue. More investigation is warranted if an answer is to be found.

There is much confusion in the literature regarding the role of vaginal cultures. Kaufman and Friedrich have demonstrated that the wet smear accurately identifies the most common organisms: Candida, Trichomonas, and Gardnerella. They also noted that the Lactobacillus was easily identifiable through a wet mount.¹⁸

Except to confirm a diagnosis of chlamydia, gonor-

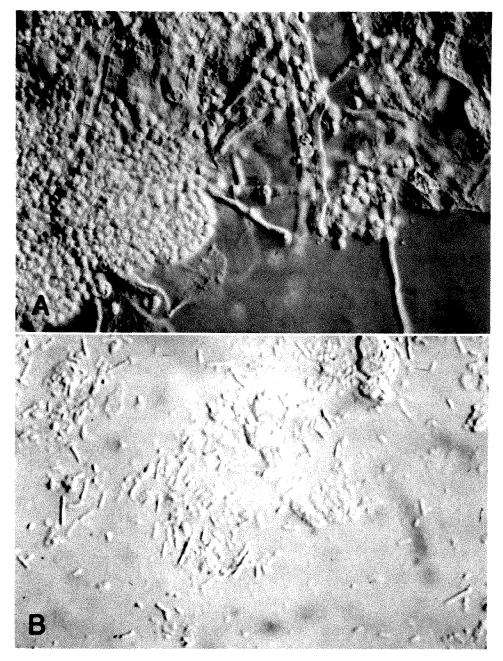

Fig. 1. Symptomatically confused with candidiasis, cytolytic vaginosis looks much different with the Nomarski microscope. **A,** *Candida albicans* seen at 200 power. Note buds and pseudohyphae. **B,** Cytolytic vaginosis seen at 400 power. Note increase in lactobacilli.

rhea, or mycoplasm, we rarely use cultures for the diagnosis of vaginitis. To date, we have personally examined more than 10,000 wet smears with Phase and Nomarski microscopy and are firmly convinced that the microcosm of the vaginal flora is better studied in its natural milieu than in artificial laboratory cultures.

We suggest criteria for the evaluation of a wet smear:

- 1. A 5-minute search under 200 to 400 power magnification is required before stating a slide is neg-
- ative. The microscope should be of modern quality and a cover slip of proper thickness is an essential part of the system. Examination under oil immersion is almost never needed.
- 2. The wet smear should be taken from the vaginal side walls or the pool or both. It should not be taken from the cervix, except for cultures, and once obtained, should be examined promptly by an experienced examiner. The cotton or Dacron

swab should be mixed with four or five drops of normal saline or Ringer's lactated solution and placed in either a test tube or a paper cup. The sample should then be applied directly to the slide. An undiluted smear is often far too thick to interpret properly and dries too easily.

- 3. We find that potassium hydroxide is seldom necessary to diagnose *Candida* in the wet smear if the observer has spent time in practice reading. Potassium hydroxide frequently damages the objective lenses of the microscope by etching the glass and causing a loss of resolution and contrast in the specimen.
- 4. The Phase or Nomarski microscope gives an entirely new perspective in evaluating the wet smear (Fig. 1). The study of living vaginal organisms is, in our opinion, the most logical way of studying the ecology of the female lower genital tract. There is no comparison with the fixed slide, as in Papanicolaou preparations or Gram's stains, with that obtained in vivo by Nomarski or Phase equipment. We strongly urge gynecologists to become acquainted with this modern method of microscopy.

Cytolytic vaginosis is an easily diagnosed, easily treated entity that requires no elaborate laboratory tests, uses low-cost treatment with agents found in most households, and is totally without risk to the patient. Our criteria for diagnosis of this condition include a high index of suspicion; absence of Trichomonas, Gardnerella, or Candida on wet smear; an increased number of lactobacilli (often adherent to the intermediate epithelial cell, and to the inexperienced observer are often confused with the clue cell of bacterial vaginosis); a paucity of white blood cells; evidence of cytolysis with bare or naked intermediate nuclei; discharge (which may be white, frothy, or cheesy); and a pH between 3.5 to 4.5. The patient who presents with cytolytic vaginosis complains of pruritus, dyspareunia, vulvar dysuria, and cyclic increase in symptoms that are more pronounced in the luteal phase. She generally carries a shopping bag full of partially used medications, many of which are generic clones, that have failed to cure or even alleviate her condition.

Treatment for cytolytic vaginosis consists of increasing the pH of the vagina by means of sodium bicarbonate douches. We recommend a douching solution of 30 to 60 gm of sodium bicarbonate to 1 L of warm water two to three times per week and then once or twice a week as needed. The patient can also be instructed to start douching 24 to 48 hours before the anticipated onset of symptoms.

The exogenous addition and increased concentration of lactobacilli to reestablish the so-called ecologic bal-

ance of the vagina has no scientific relevance. This is also true for the indiscriminate use of vinegar-andwater douches. To add more lactobacilli or to use vinegar douches that further lower the vaginal pH in a patient who already exhibits a low vaginal pH, as well as an overgrowth of *Lactobacillus*, will only increase the symptoms. Yogurt, instilled into the vagina, is also of dubious value as therapy for vaginitis.¹⁹

It appears that the *Lactobacillus*, either alone or in conjunction with other bacteria, seems to be responsible for the signs and symptoms of cytolytic vaginosis. Regardless of the mechanism, a clinical entity exists that causes discharge and burning and is characterized by a profusion of lactobacilli with dissolution of the cytoplasm of the intermediate vaginal epithelium. The authors believe that use of the more sophisticated Phase and Nomarski microscopes will result in greater cost containment and more prompt and accurate diagnosis. This will reduce the reservoir of patients who have become emotionally crippled by this nonlethal but debilitating condition called cytolytic vaginosis.

There are many unanswered questions concerning this entity. We realize that there are insufficient data for statistical evaluation. The scope of the study has been directed toward qualitative interpretation rather than quantitative hard data. The question of pH change and its duration, as provided by baking soda douches, needs to be addressed. The authors plan such an investigation.

Postpartum vaginal atrophy

Peter M. Wisniewski, MD, and Edward J. Wilkinson, MD

Philadelphia, Pennsylvania, and Gainesville, Florida

Postpartum vaginal atrophy has been briefly noted without adequate clinical description. We present a study of 215 puerperas at a scheduled 4-week postpartum visit, investigating colorpHast vaginal pH, vestibular cotton swab testing, vaginal wall tenderness, and both fixed and wet mount cytologic studies. Thirty-seven patients with vaginal atrophy (17.2%) had a mean pH of 6.55 with a mean maturation index of 49.2% parabasal, 46.5% intermediate, and 4.3% superficial cells. Eighty patients (37.2%) served as control subjects, with a mean maturation index of 0.3% parabasal, 73.6% intermediate, and 26.1% superficial cells, and a mean vaginal pH of 4.68. Ninety-eight patients (45.6%) were excluded for multiple confounding conditions, the most common of which was bacterial vaginosis in 37 (17.2%). This study demonstrates the existence of postpartum vaginal atrophy, notes lactation as an apparent causal factor, and establishes a statistically significant (p < 0.0001) relationship between vaginal pH and maturation index. Further studies are needed to confirm therapeutic efficacy of estrogens. (AM J OBSTET GYNECOL 1991;165:1249-54.)

Key words: Atrophic vaginitis, vaginal maturation index and pH, lactation, vestibulitis

From rupture of membranes to resumption of ovarian function, the vulvovaginal ecosystem is subjected to an alkaline environment, relative estrogen deprivation, and the mechanical trauma of childbirth. Although various elements of these changes have occasionally been noted in the literature, ¹⁻⁶ very little clinical information about the puerperal atrophic changes in the vulva and vagina is available. Our earlier pilot study⁷ evaluated

112 patients at 6- to 14-week postpartum visits. Fourteen patients (12.5%) had dyspareunia, vaginal stinging, dysuria, vaginal tightness, tenderness on speculum examination, vaginal color change, or scant discharge. Their mean vaginal pH was 6.3 compared with a control group at 4.7, establishing elevated pH as a sign of this condition. Three patients noted similar symptoms after previous pregnancies. Eleven of the 14 patients were treated with intravaginal estrogen, and the condition resolved within 28 days. The conditions of three untreated patients resolved in 56 to 180 days with oral contraception or resumption of ovarian function despite continuing lactation.

Progressing from the shortcomings of that study, this effort was initiated at a scheduled 4-week postpartum

visit that investigated vestibular cotton swab testing,⁸ colorpHast vaginal pH,⁹ vaginal wall tenderness, and both fixed and wet mount cytologic studies. Elevated vaginal pH was used as the most objective of the previously recognized inclusion criteria. The goals were to more clearly appreciate the clinical parameters of vulvovaginal postpartum atrophy, to establish the significance of the relationship between the cytologic maturation index (MI) and vaginal pH, and to suggest treatment.

Material and methods

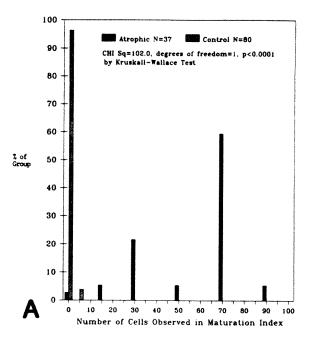

Two hundred fifteen puerperas delivered in a solo private Philadelphia obstetric practice who returned to the office for a scheduled 4-week postpartum visit between March 1989 and June 1990 were entered into this study. Noting a published statement 10 on absent reported risk, the protocol and ongoing study were approved and monitored by the institutional review board of the Pennsylvania Hospital, Philadelphia, Pa. A thorough interval history was taken with special attention directed at eliciting vaginal stinging or burning, vaginal tightness, dysuria, and dyspareunia, both insertion and deep thrust, and also postcoital dyspareunia. Physical examination included breasts, abdomen, cervical Papanicolaou smear, and bimanual examination. We also incorporated vestibular cotton swab testing, colorpHast anterolateral vaginal wall pH, elicitation of tenderness on gentle scraping of the lateral vaginal walls with a plastic scraper, lateral vaginal wallfixed cytologic specimens later stained with the Papanicolaou technique, fresh specimens of the lateral vaginal wall examined immediately in normal saline wet mount preparation, and urine culture and sensitivity.

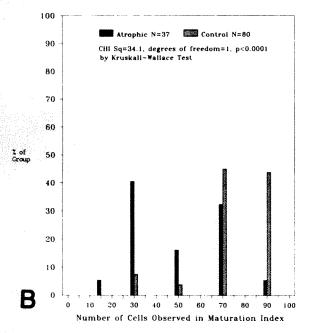

Considering that all patients recently had negative test results or had been successfully treated for syphilis, gonorrhea, and chlamydia during pregnancy, no additional effort to detect these conditions was made. Inclusion criteria for this study were a vaginal pH greater than or equal to 5.3 and at least one symptom (dysuria, tightness, stinging, burning, or any dyspareunia) and/or at least one sign (scant vaginal discharge, red or pallid vaginal mucosa, at least a two-site positive vestibular cotton swab test, or tenderness elicited on gentle scraping of the lateral vaginal wall). Because of the complexity of the vulvovaginal milieu, great care was taken to attempt to exclude all other confounding variables. Exclusion criteria for this study were bacterial vaginosis, trichomoniasis, candidiasis, cytolytic vaginosis, cervical intraepithelial neoplasia, human papillomavirus disease, active herpes simplex virus, symptomatic cystitis, incomplete healing at episiotomy or laceration sites, ovulation (in nonlactating patients who came to the office more than 40 days post partum), and other mechanical factors, such as active bleeding, douching, or coitus within 6 hours. Air-dried smears and endometrial, cervical, or introital-contaminated smears were also excluded. Control subjects were all remaining patients neither included nor excluded. The cytologic part of the study was performed independently and blindly in Gainesville, Fla.

All included patients were provided conjugated estrogen vaginal cream at a dose of 2 gm per vagina twice a week and instructed to return at 14-day intervals until no evidence of atrophy remained. Excluded patients were treated appropriately where necessary. Statistical analysis used the modifications of the χ^2 test as noted below.

Results

A total of 215 patients returned for their scheduled postpartum visit. Thirty-seven patients (17.2%) merited placement in the included, atrophic group. This group had a mean vaginal pH of 6.55 with a mean MI of 48.19% parabasal, 46.49% intermediate, and 4.32% superficial cells. The symptoms noted in this group in-

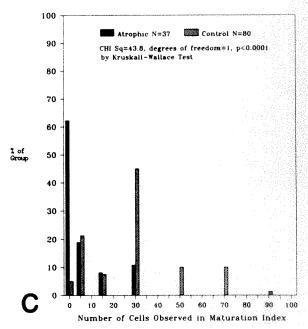

Fig. 3. Graphic representations of cytologic data in the study group by MI component.

cluded dyspareunia in 8 of 10 patients (80%) who attempted coitus, 6 (16.2%) had vaginal stinging, 4 (10.8%) had vaginal tightness, and 1 (3%) had dysuria. Four (10.8%) had experienced similar symptoms after previous pregnancies. Epithelial vestibular vaginal color change was the most frequent sign elicited from the included group of 35 of 37 patients (94.6%). Thirty-three patients showed red change (Fig. 1, p. 1227), whereas 2 had pallid change (Fig. 2, p. 1227). Ten-

derness of the lateral vaginal wall was elicited in 33 patients (89.2%) of this group. Vestibular tenderness by swab testing was present in eight subjects (21.7%) of this group.

Eighty patients (37.2% of total) remained in the control group. This group had a mean vaginal pH of 4.68 with a mean MI of 0.31% parabasal, 73.63% intermediate, and 26.06% superficial cells. Eighteen (22.5%) of these control subjects had an elevated pH between 5.3

and 5.9 without signs or symptoms, whereas 29 subjects (36.3%) had signs or symptoms without an elevated pH. The symptoms noted in this group included dyspareunia in 4 of 31 patients (12.9%) who attempted coitus and vaginal tightness in 4 (5%). Signs elicited in this group included two subjects (2.5%) with red vaginal mucosa, three (3.8%) with lateral vaginal wall tenderness, and eight (10%) who had vestibular swab tenderness.

Ninety-eight patients (45.6% of total) were excluded for the following reasons: 37 (37.8%) for bacterial vaginosis, 21 (21.4%) for unreliable cytologic findings or pH, 7 (7.1%) for symptomatic cystitis, 7 (7.1%) for cervical intraepithelial papillomavirus disease, 7 (7.1%) for poor healing at episiotomy or laceration sites, 6 (6.2%), who returned between 40 and 70 days post partum for signs of imminent ovulation, 6 (6.2%) for trichomoniasis, 4 (4.1%), who came at a mean 53.5 days post partum for candidiasis, and 3 (3.3%) for cytolytic vaginosis (Döderlein cytolysis). Fifteen patients had multifactorial exclusion criteria.

A comparison of the vaginal pH used as the selection criteria between the inclusion and control groups is given in Table I. Comparison of the MI profiles between the two groups in Fig. 3, A through C, demonstrates a marked left shift, with increasing percentages of parabasal cells and decreasing superifical cells, which defined the inclusion group as atrophic. The infant feeding comparison described in Table II demonstrates a significant correlation between lactation and postpartum vaginal atrophy. Of note, only 67.6% of nursing mothers had vaginal atrophy, whereas 32.4% of patients with atrophy were not lactating. Comparison of route of delivery in Table III demonstrates no significant difference in development of postpartum vaginal atrophy. The therapeutic response to intravaginal conjugated estrogen cream is noted in Table IV. Although all treated patients had resolution within 40 days, spontaneous remission and decreasing lactation may account for a portion of the improvement. The vaginal

estrogen cream did not cause any reported systemic effects in either nursing mothers or their infants.

Comment

Kauffman et al.11 define vaginal senile atrophy as a condition with a left shift in the cytologic vaginal MI and increasing percentages of intermediate and parabasal cells and decreasing superficial cells caused by withdrawal of estrogen. They note most patients deny symptoms, although dysuria, external burning, tenderness, dyspareunia, slight discharge, and pruritus may accompany this condition. Signs include vaginal mucosal color change from pink to diffuse redness to pallid, traumatic vulnerability to coitus or speculum examination, petechiae, and the eventual disappearance of folds and rugae. A scant discharge is present with increased parabasal cells, white blood cells, and absent lactobacilli. Lateral vaginal pH is between 6 and 7. A subset of vaginal atrophism resulting from radiation therapy causes more severe changes. The causes include direct radiation and pressure damage and irradiation castration. Topical and/or systemic estrogen is the treatment of choice for both conditions.

In 1944 Rakoff et al.1 noted that the decrease in ovarian activity during perimenopause was accompanied by a rise in vaginal pH progressing to neutral (7) levels during menopause. In 1955 Lang² observed that the puerperal vagina is bathed with alkaline lochia. In 1958 Kauffmann et al.3 noted parabasal cells in postpartum cervical cytologic studies analogous to those seen in senile atrophic vaginitis. Masters and Johnson⁴ in 1966 published observations on visual examination of three lactating and three nonlactating mothers at 4, 8, and 12 weeks post partum. They noted a decrease in physiologic response, flattened rugal patterns, and a "senile"-appearing light pink color change at 4 and 8 weeks. They also noted that nursing patients had a "steroid starvation pattern." Recovery was appreciated at 12 weeks. They also conducted 12-week interviews

with 101 puerperas in whom 11 (10.9%) noted vaginal tightness and 47 (46.5%) noted irritation or dyspareunia. They concluded "... for at least 4 weeks after delivery, all women are essentially castrates so far as ovarian function is concerned...." More recently, Friedrich⁵ noted alkaline change in the vagina with dyspareunia during lactation and suggested twice-weekly conjugated estrogen vaginal cream. Giuntoli et al.6 observed vaginal colposcopic and cytologic atrophic changes during the postpartum period and noted their continuation for prolonged periods in nursing mothers. The postpartum condition described in the present study fulfills nearly all of the criteria of Kauffman et al.11 for vaginal atrophy and should be considered as the third subset of that entity. Although white blood cells are frequently present in the puerperal vagina, they may be of lochial origin, making the use of the term "vaginitis" questionable. Although the pH selection cutoff at 5.3 may have been somewhat low, scheduling the initial postpartum visit at 4 weeks produced clearer results than our pilot study.7 From the exclusion group, we note the 17.2% rate of bacterial vaginosis is comparable with similar studies^{12, 18} with 14% and 22% rates. Of clinical interest, fixed stained cytologic studies were almost twice as effective in the diagnosis of this condition, although the homogenous discharge and bacterial corkscrew wet mount patterns described by Thomason et al.14,15 were not used. The heavy alkaline cervical discharge that accompanies spinnbarkeit and ferning during the actual hours of ovulation invalidating these vaginal pH readings has received scant recent notice in the literature. The reliable colorpHast, indicator strips, and an improving appreciation of the vaginal ecosystem may facilitate these studies. The relative absence (1.86%) and delayed appearance (53.5 mean postpartum days) of Candida in these patients may reflect vaginal alkalinity as an inhibiting factor in this infection.

The comparison of control and atrophic patients by type of infant feeding (Table II) indicates a statistically significant (p < 0.0001) correlation between vaginal

atrophy and nursing. That this relationship was not universal may be from variations in individual estrogen receptors and peripheral conversion of androstenedione to estrone in fatty tissue. Comparison of symptoms seems to indicate that the dyspareunia present in 12.9% of control subjects and 80% of atrophic patients attempting coitus may have some diagnostic significance. However, several signs were even more promising. Mucosal red or pallid color change was present in 94.59% of the atrophic group versus 2.5% of control subjects. Lateral vaginal wall tenderness was appreciated in 89.19% of atrophic patients versus only 3.75% of control subjects. The color changes are caused by a thinning of the vaginal mucosa. The tenderness in the usually poorly sensitive lateral vaginal wall may also reflect a thinner vaginal mucosa exposed to an irritative alkaline environment. The vestibular swab tenderness seen in 21.62% of patients with atrophy but also 10% of control subjects seems less specific. First appreciated in the enigmatic vulvar vestibulitis, this sign may be the final common pathway for many different types of vestibular irritation. Its presence in the alkaline puerperal vestibule may indicate a vulvar component to vaginal atrophy. However, more data will be required to be convincing.

The similarities in both groups in mode of delivery (Table III) would argue that mechanical trauma is not a statistically significant factor in vaginal atrophy. The therapeutic response noted in Table IV is gratifying but uncontrolled for placebo effect. Double-blinded placebo/estrogen vaginal cream studies will be required to demonstrate therapeutic effectiveness.

Of all the results in this study, the relationship between vaginal pH and MI may be the most significant not only in the p value (p < 0.0001) but also in broader measure. The MI has been criticized16 for lack of precision, sensitivity, specificity, and accuracy. However, the studies17, 18 that generated this criticism were based on menopausal symptoms, which are denied by most patients and full of subjective variation. In vaginal atrophy, symptoms may be considerably less reliable than the signs (color change, pH, MI, scant discharge, absent lactobacilli, and vaginal tenderness). We have been able to demonstrate a significant relationship between vaginal pH and MI. Using similar methods, other vaginal relationships may be amenable to study. Indeed, the development of an inexpensive (colorpHast strips at 8 cents each) indicator for estrogen replacement that uses vaginal pH would seem worthwhile. Finally, this study taught us that accomplishment of reproducible scientific work dealing with the human vagina necessitates separating out many dependent variables in an attempt to isolate those factors that initiate change.

We gratefully acknowledge the contributions of our colleagues in the International Society for the Study of Vulvar Disease, on whose shoulders this work stands. In particular, Raymond H. Kauffmann, MD, and the late Eduard G. Friedrich, Jr., MD, were mentors for the experimental design. Greg Maislin, MS, MA, of Biomedical Statistical Computing, performed the statistical calculations. Michael J. Warhol, MD, and Thomas V. Sedlacek, MD, provided manuscript review. Charlene M. Lewis, IAC, ASCP, CT, provided cytotechnologist support.

Vaginal cancer: The role of infectious and environmental factors

Maria J. Merino, MD

Bethesda, Maryland

Primary cancers of the vagina are rare. They comprise 1% to 2% of all gynecologic malignancies and occur predominantly in older women. The diagnosis of primary carcinoma of the vagina requires that the cervix and vulva be intact and that no clinical evidence of other primary tumors exist. Approximately 90% of all vaginal tumors are squamous cell in type on histologic examination. Adenocarcinoma, which is much less common (2% to 4%), is seen primarily in younger women with in utero exposure to diethylstilbestrol. In addition to exposure to diethylstilbestrol, other environmental factors have been associated with the development of vaginal tumors, including chronic irritation from pessaries, previous hysterectomy for benign disease, immunosuppression therapy, cervical irradiation, and endometriosis. Infectious causes seem to play an even more pernicious role in vaginal cancer. The two agents most often implicated are herpes simplex virus and human papillomavirus. These viruses appear to serve as cofactors in the inducement of various genital cancers, working together or with environmental agents such as diethylstilbestrol and host-related genetic abnormalities. The prognosis of vaginal cancer depends on the stage of the disease, with an overall 5-year survival rate of 80% to 90% for early stages. (Am J Obstet Gynecol 1991;165:1255-62.)

Key words: Vaginal cancer, herpes simplex virus, human papillomavirus, diethylstilbestrol, cervical cancer

Of all genital cancers in women, primary carcinoma of the vagina is second only to cancer of the fallopian tubes in its rarity. Vaginal tumors account for approximately 1% to 2% of all gynecologic malignancies, with an estimated incidence of 300 to 700 new cases each year. Secondary malignancies are, by contrast, quite common and make up 80% to 90% of all tumors in this site. This is probably because of the anatomic location of the vagina, which lies dorsal to the urinary bladder and ventral to the rectum. Primary tumors in these locations can involve the vagina by direct spread or by lymphatic dissemination.

Diagnosis and presentation

Primary vaginal cancer is a disease of older women, with the peak incidence occurring during the sixth and seventh decades. Only about 15% of patients are 50 years of age or younger.⁴

Symptoms of the disease may vary. The most common clinical complaint is that of irregular bleeding, but leukorrhea, or especially in advanced cases, pelvic pain, can also occur. However, many patients have no symp-

From the National Cancer Institute, National Institutes of Health. Reprint requests: Maria J. Merino, MD, Chief of Surgical Pathology, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bldg. 10, Rm. 2N-212, 9000 Rockville Pike, Bethesda, MD 20892.
6/0/32677

toms, and a diagnosis is made during the investigation of other conditions, such as uterine prolapse, rectal or urinary fistulas, an abnormal Papanicolaou smear, or less commonly by a palpable mass. Tumors are usually located in the vault or upper third of the vagina with a slight predilection for the posterior wall. To qualify as a primary vaginal squamous cell carcinoma, some authors require that the cervix and vulva be without tumors and that no clinical evidence of tumors exists elsewhere.

Tumor traits

The upper vagina and cervix share an identical stratified squamous epithelium, and each structure is highly sensitive to hormonal stimulation. Therefore it is not surprising that on histologic examination, lesions in the upper vagina closely resemble those found in the cervix, regardless of whether the tumor is in situ or invasive.

The histologic appearance of vaginal tumors varies. Approximately 90% are squamous cell carcinomas and may present as either in situ or invasive lesions.²

Adenocarcinomas account for 2% to 4% of the tumors and are typically seen in patients who have been exposed to diethylstilbestrol (DES). Other primary malignant tumors include malignant melanoma, sarcomas, and embryonal rhabdomyosarcoma in children.

Vaginal squamous cell carcinoma may have different

Table I. Predisposing factors in the pathogenesis of vaginal cancer

Strong association
HPV (may be a cofactor with HSV)
DES exposure in utero
Immunosuppression therapy
Chronic irritation (e.g., from pessaries)
Irradiation for cervical disease
Possible association
HSV (may be a cofactor with HPV)
Previous hysterectomy for benign disease
Unknown association
Cigarette smoke
Other vaginal infections (e.g., cytomegalovirus)

appearances on gross examination; it can be papillary, growing in a cauliflower-like fashion, infiltrative or nodular, and ulcerative in type with raised borders and shallow ulcerated beds.

Most squamous carcinomas are composed of atypical and polymorphic tumor cells in different degrees of differentiation with dense eosinophilic cytoplasm and large nuclei with irregular chromatin distribution. Three histologic grades are recognized; well differentiated, moderately differentiated, and poorly differentiated. The tumors can also be classified as keratinizing if there is evidence of intracytoplasmic keratin or pearl formation and nonkeratinizing if this differentiation is lacking. Other varieties, such as spindle cell or verrucous carcinoma, are rare.

The fact that vaginal tumors resemble those in nearby structures is clinically significant, because frequently cancer at one site prefigures disease at the corresponding location. The link between tumors is so strong that many authors do not accept a vaginal tumor as primary if it occurs in a patient with history of cervical cancer. In general, it is accepted that patients with a previous history of cervical cancer should have a 5-year disease-free interval after treatment for invasive cancer and a 2-year interval between carcinoma in situ and the newly diagnosed vaginal lesion.⁴

Consequently, careful scrutiny and follow-up are necessary in patients with previous genital cancers. Extra vigilance is warranted even in women with conditions that are associated with cancer, such as cervical dysplasia or infection with human papillomavirus (HPV).

Predisposing factors

Nonviral. The literature cites numerous factors that may predispose women, particularly older women, to vaginal cancer (Table I). One suggested factor is chronic irritation. Chronic or irritant vaginitis is not frequent today, but it was commonly seen when pes-

saries were used as therapeutic devices for uterine prolapse. The vaginal mucosa shows marked hyperkeratosis or thickening, acanthosis, and inflammation. Pessaries left in place for long periods of time produce metaplastic and subsequent dysplastic alterations of the squamous mucosa. Today contact vaginitis is more likely caused by secondary chemical irritation and douches.

Previous hysterectomy for benign disease may also be a factor in primary vaginal cancer. In 1984 Bell et al.5 reported a 36% incidence of vaginal carcinoma in 87 women who had undergone hysterectomy for benign disease. Hoffman et al.6 subsequently found that 22 of 26 women with vaginal intraepithelial neoplasia had been so operated. Seven of the hysterectomies were for benign disease, whereas 15 were for cervical intraepithelial neoplasia or cancer. Two of the women in this series later had invasive squamous cell carcinoma of the vagina. More recently, however, Herman et al.7 have cast doubt on the association between hysterectomy and ensuing vaginal cancer. To investigate this relationship, they compared 49 patients with vaginal cancer with 49 control subjects matched for age, race, and a prior history of dysplasia or neoplasia. They concluded that hysterectomy was a very low risk factor for the development of vaginal cancer.7

A strong link also appears to exist between primary vaginal cancer and endometriosis. As is well known, ectopic endometrial tissue responds to hormonal stimulation and thus is capable of proliferating and giving rise to hyperplasias and carcinomas. A few cases have been reported in which ectopic tissue produced primary adenocarcinoma of the vagina, usually of the endometrioid type.⁸

Furthermore, clear cell adenocarcinoma of the vagina is well recognized in young women who were exposed in utero to the synthetic estrogen DES. The risk has recently been found to be higher for those patients whose mothers received DES before the twelfth week of gestation. This true primary vaginal neoplasm occurs in young women between 15 and 25 years of age, who frequently have associated vaginal adenosis, vaginal adhesions, or both. Many patients exposed to DES have an extensive transformation zone in the cervix and vagina, which on colposcopic evaluation may show mosaicism, punctuation, and areas of white epithelium representing squamous metaplasia. Benign glandular columnar epithelium is present in areas of adenosis, and whether benign adenosis evolves to carcinoma is still controversial. Carcinomas arising in DES-exposed patients may have several histologic patterns: tubulocystic, which is seen more frequently in older women and is associated with good 5-year survival, and solid,

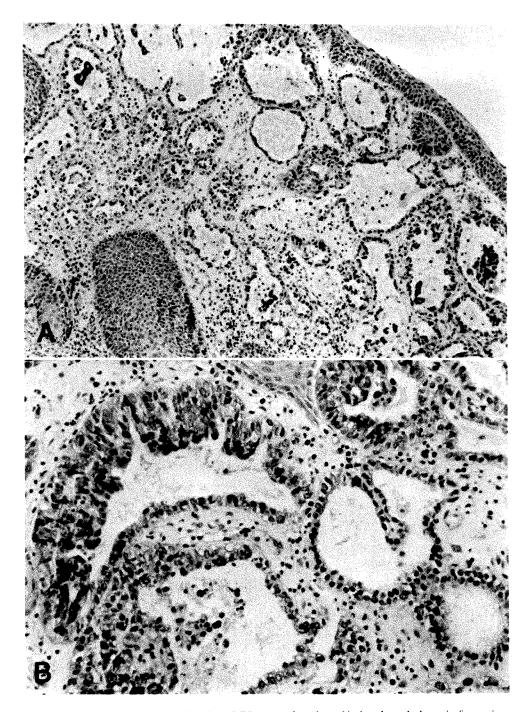

Fig. 1. A, Adenocarcinoma arising in a DES-exposed patient. Notice the tubulocystic formation. (Hematoxylin-eosin stain; ×200.) B, Cells with prominent nucleus lining the glandular structures. (Hematoxylin-eosin; magnification ×250.)

papillary, or mixed variants, which are seen in young girls and are associated with a poor prognosis. The tumors are composed of cells with clear cytoplasm and prominant round nucleus. Some cells may acquire a characteristic appearance with a large nucleus, prominant nucleolus, and scant cytoplasm (hobnail cells) (Fig. 1).9

Although relatively few DES-exposed women develop clear cell adenocarcinoma (1 per 1000 from birth through age 34 years),10 several factors apparently increase the risk of cancer in individual patients. These include a maternal history of prior miscarriage, exposure to DES in early gestation, birth in the fall, and prematurity.11 Given the low risk of clear cell adeno-

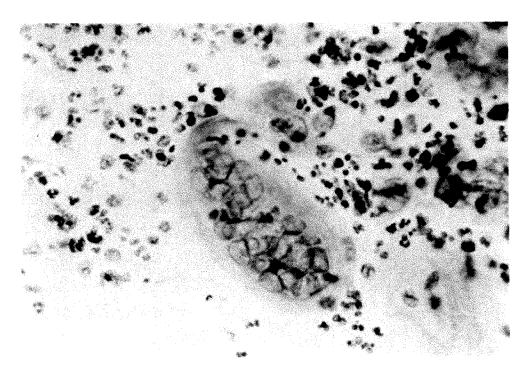

Fig. 2. Papanicolaou smear showing a multinucleated giant cell with washed-out nuclei, characteristic of herpes infection.

carcinoma, Melnick et al.¹² have postulated that DES is an incomplete carcinogen and that other cofactors may be involved in the pathogenesis of this disease. It now appears that many DES daughters who develop clear cell adenocarcinoma are also infected with HPV.

As with DES, the association between cervical cancer and subsequent vaginal cancer is strong. However, whether vaginal carcinoma represents a primary cancer or a late recurrence of the first disease is nearly impossible to know when the vaginal tumor arises 5 or more years after the cervical cancer. In a retrospective study of 763 women treated for invasive carcinoma of the cervix, Kapp et al. ¹³ found that patients were 14 times more likely to develop subsequent neoplasms involving the vagina or vulva than other body sites. Although it is very possible that the development of vaginal tumors merely reflects multiple neoplastic syndrome, it is interesting to note that most of the women in the study of Kapp et al. had been treated with ionizing radiation.

Many investigators believe that radiation therapy for cervical disease can induce vaginal cancer. It is well known that the amount of radiation reaching the vagina in such circumstances is not enough to kill cells but is sufficient to have a mutagenic effect. Estimates are that about 50% of patients who undergo irradiation may develop dysplasias in situ carcinomas.

In such patients the resultant vaginal cancer would be considered primary. Using a 5-year or more interval and cytologic smears to differentiate primary from secondary vaginal cancers, Murad et al.15 concluded that the risk of cancer may be greater after irradiation of a cervical carcinoma. In another study, Pride and Buchler¹⁶ found that women with cervical carcinoma ran a small but significant risk of radiation-induced cancer of the upper vagina 10 or more years after treatment.16-19 Okagaki et al.20 studied the deoxyribonucleic acid (DNA) content of cells in 60 patients identified as having dysplasias after radiation treatment. The cells were classified as diploid, aneuploid, or polyploid, and they correlated their findings with survival. Patients with aneuploid tumors had shorter survival times and earlier recurrences; thus they concluded that the presence of aneuploid cellular content was indicative of a poor prognosis.20

Of course, it is possible that primary vaginal tumors are really more common than estimated but that by the time of discovery cervical involvement leads most clinicians to assume that they are dealing with a primary cancer of the cervix. Nevertheless whether this is true, vaginal smears should be performed frequently in women who previously had irradiation for cervical cancer. In such patients flow cytometry may help determine the DNA population of the cells.

Vigilance may also be warranted in women who have undergone immunosuppression therapy, because in situ vaginal cancer has been found in organ-recipient patients and those patients with conditions such as

Fig. 3. Papanicolaou smear showing cellular changes consistent with HPV infection: perinuclear halos, enlarged nucleous, binucleation, and dense orangiophylic and granular cytoplasm.

chronic granulomatous disease.²¹ The associated tumors have occurred either as an isolated process or as part of the neoplastic syndrome of the lower genital tract. Immunosuppression is also believed to increase the risk of certain viral infections associated with genital cancers.

Viral. Viral infection, particularly with herpes simplex virus (HSV) or HPV, has been increasingly implicated in the pathogenesis of vaginal cancer. These infections follow the pattern of venereal diseases that can affect both men and women; except in rare cases, they do not appear before the onset of sexual activity.

HSV derives from a large class of DNA viruses that include varicella zoster, cytomegalovirus, and Epstein-Barr virus. After viral penetration of the human cell wall, the nucleocapsid is released, and the viral DNA enters the nucleus of the host cell. The dorsal spinal ganglia are believed to harbor latent viruses, which when activated travel down the axons and produce lesions in the skin supplied by the sensory neuron. Infections occurring above the waist are generally caused by HSV 1, whereas those occurring below the waist are generally caused by HSV 2; however, there is significant crossover between viral types in these two areas. Indeed, recent reports point to the increasing frequency with which HSV 1 is diagnosed as the cause of genital lesions.²²

In 1966 Naib et al.²³ reported an increase in the rate of cervical cancer in women with cytologically proven

herpetic cervicitis. Later, many seroepidemiologic studies, although not all, confirmed the prevalence of HSV 2 antibodies or antigens among women with cervical neoplasia. However, it has since been shown that when the data are controlled for sexuality, the association between these lesions and HSV 2 is not significant. Hence it is possible that these findings merely reflect an earlier age of first intercourse and multiple sexual partners. Moreover, no causal link has been established between HSV and genital cancers. Still, given the epidemiologic association, it is recommended that women with genital HSV infections be examined annually by Papanicolaou smear. HSV is readily identifiable in Papanicolaou smears as a multinucleated giant cell with a multiple, washed-out nuclei (Fig. 2).

In recent years attention has shifted from HSV to HPV as an etiologic factor in the development of gynecologic cancers, particularly in younger women. Several lines of evidence—epidemiologic, clinical and experimental—support the association.

With its icosahedral virion capsids and circular double-stranded DNA, HPV forms a subgroup of the papovavirus family. More than 50 distinct types of HPV exist, 12 of which are associated with lesions of the anogenital tracts. Types 6 and 11 are often found in condyloma acuminata or low-grade lesions. ²⁶ Types 16, 18, 31, 33, 35, 39, 45, and 52 have been linked to anogenital cancers²⁷; types 16 and 18 have been closely associated with squamous cell carcinomas. ^{26, 28} In ma-

Fig. 4. Condylomatous vaginitis. The squamous mucosa is thickened, and koilocytes can be identified in the surface epithelium. (Hematoxylin-eosin; magnification $\times 150$.)

lignant transformation, the virus becomes integrated into the host cell genome. As a result, abnormalities of host cell DNA replication arise, and a marked tendency toward aneuploidy develops. Animal studies show that the rate of malignant conversion depends on the viral strain, host species, and individual response.

HPV infections of the anogenital area have increased dramatically during the past 2 decades; the estimated incidence is three times that of genital herpes in the United States.²⁹ Studies have shown that women with a history of these infections are four times more likely to develop cervical carcinoma in situ than their uninfected counterparts.³⁰ The natural history of the progression to intraepithelial neoplasias is best understood in cervical lesions.^{31,35} Whether a lesion regresses, remains the same, or progresses depends on various factors, such as the histologic grade of the tumor and the HPV type. With highgrade lesions, there is almost total loss of squamous maturation and a higher risk of progression to invasive cancer.³³

Although infection with HPV appears necessary for the development of malignancy, some authors argue for the involvement of additional environmental or host-related cofactors.^{27, 31, 36} Popescu and DiPaolo³⁶ have proposed that HPV integration on the mammalian genome increases genetic instability and uncontrolled cell division, thereby making the cell more sus-

ceptible to cofactors that complete neoplastic conversion. A case has also been made for a possible link between HSV and HPV in the development of anogenital cancers.³⁷

That viruses may serve as cofactors in the pathogenesis of cervical cancer was demonstrated in a prospective study of 950 DES daughters by Adams et al.²² They found that HSV 1 antibody levels were significantly higher in the 23 women who developed cervical intraepithelial neoplasia during the study than in a well-matched control population. They also found that 73 of patients with DES who were negative for HPV when the study began became infected by its end. These findings suggest that HSV 2 infection may precede HPV infection and that the two may be essential to inducing squamous cell carcinoma. Certainly, the concept of cofactors is intriguing, because HPV alone can be found in a significant percentage of women with cytologically normal results.^{29, 32}

Various gradations of dysplasias are associated with HPV lesions (Figs. 3 through 6). The hallmark of condylomatous lesion is the presence of the koilocyte, which is a hyperchromatic, wrinkled irregular nucleus surrounded by abundant clear cytoplasm. The squamous mucosa shows various changes, such as acanthosis, papillomatosis, elongation of the rete pegs, and hyperkeratosis with or without parakeratosis. Associated dermal inflammation is also noted. The dys-

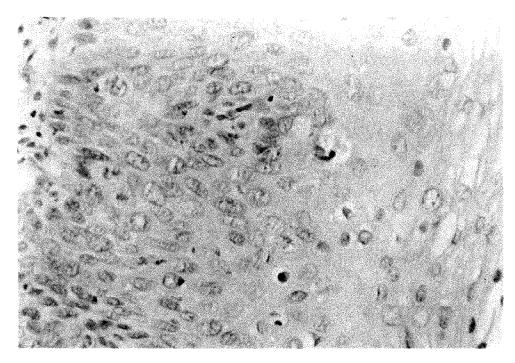

Fig. 5. Moderate dysplasia associated with HPV infection. Notice the lack of maturation of the basal cells, approaching about half the thickness of the squamous mucosa. (Hematoxylin-eosin; magnification $\times 250$.)

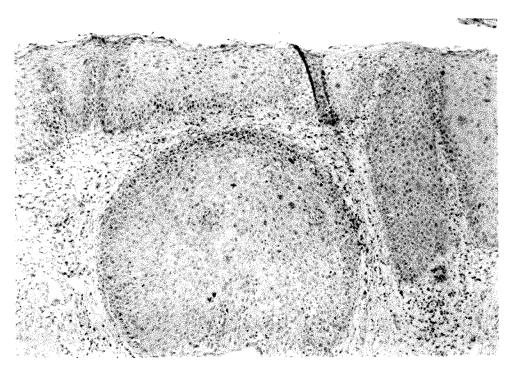

Fig. 6. Severe dysplasia in association with condylomatous changes. (Hematoxylin-eosin; magnification \times 150.)

plastic changes are similar to those that occur in the cervix.

Prognosis

The prognosis of vaginal cancer is highly dependent on the stage of the disease. The International Federation of Gynecologists and Obstetricians classifies vaginal cancer as follows:

Stage 1: Squamous carcinoma limited to the vaginal wall

Stage II: Mural extension without involvement of the pelvic side walls

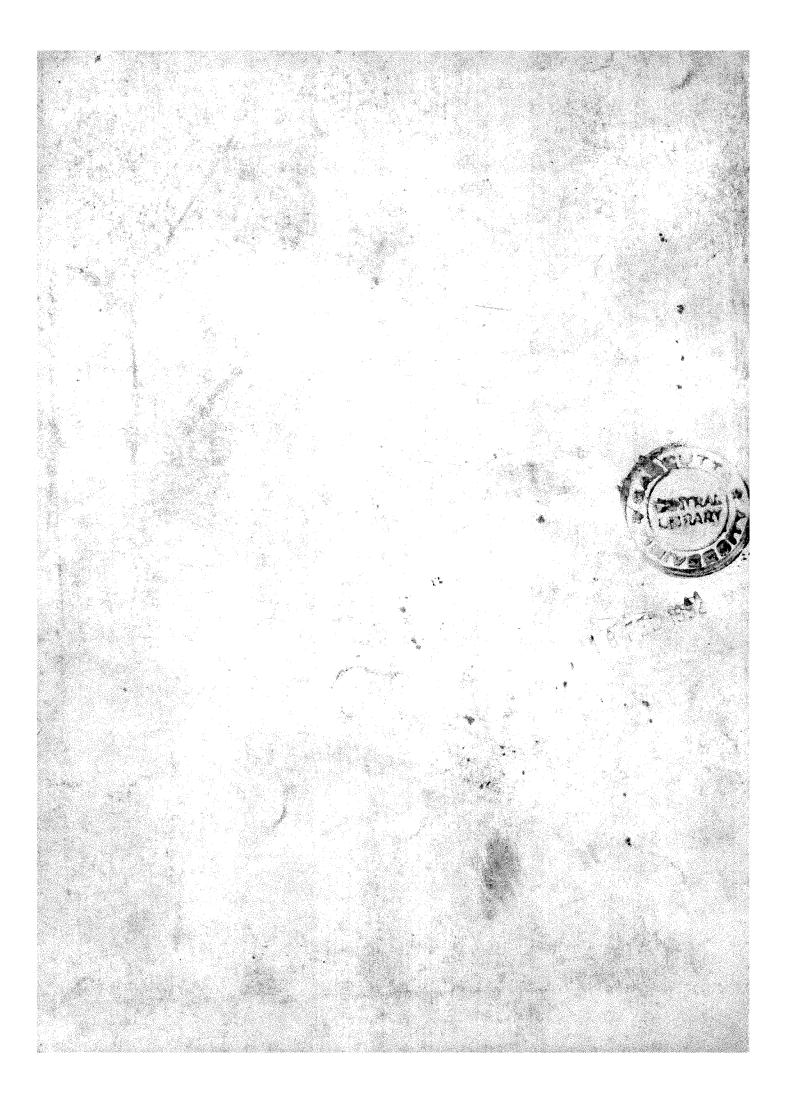

Stage III: Involvement of one or both pelvic side walls Stage IV: Tumor beyond the pelvis or involvement of the bladder or rectal mucosa

In general, the 5-year survival rate for patients with Stage I disease is approximately 80% to 90%, 50% for Stage II, and 20% for advanced Stages III and IV. Surgery and radiation therapy, either alone or in combination, are the preferred modalities of treatment.

Artist's enhancement of scanning electron microscopy: C albicans 24 hours posttreatment with butoconazole nitrate.*

When you diagnose vulvovaginal candidiasis (VVC)

FEMSTAT* Prefill (butoconazole nitrate) Vaginal Cream 2% is clinically effective against a broad spectrum of important pathogens, including *Candida albicans* and other *Candida* species, such as *C tropicalis*.

Artist's enhancement of scanning electron microscopy: Calbicans one week posttreatment with butoconazole nitrate.*

Prescribe the efficacy of 3-day therapy+

FEMSTAT achieves a microbiological cure rate of 95% with the original 3-day therapy¹ that is not confirmed to be associated with flu-like symptoms. The most common complaint with the use of FEMSTAT in clinical trials was vulvar/vaginal burning (2.3%).

1. Droegemueller W, Adamson DG, Brown D, et al. Three-day treatment with butoconazole nitrate for vulvovaginal candidiasis. *Obitat Gynetol.* 1984;64:530-534. *Micrographs on file, Syntex Laboratories, Inc. †In pregnant patients (second and third trimesters only), therapy should be extended to 6 days. Please see adjacent page for brief summary of prescribing information. © 1991 Syntex Laboratories, Inc. 813-12-196-91

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done

Mutagenesis: Mutagenicity studies were negative

Impairment of Fertility: Animal studies showed no impairment of fertility

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:

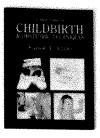

Federal law prohibits dispensing without prescription.

YOUR PATIENTS COUNT ON YOU FOR ANSWERS...

Here are two "must-have" resources to help you explain the mysteries of childbirth to your patients. Using dramatic full-color photos and ultrasound scans, these atlases provide step-by-step coverage of fetal development and childbirth.

New!

A COLOR ATLAS OF CHILDBIRTH AND **OBSTETRIC TECHNIQUES** Farook Al-Azzawi, MBChB, MA,

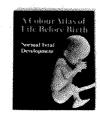

PhD, MRCOG

- Includes coverage of breech delivery, management of twins, operative vaginal delivery and the three most common types of caesarean births.
- Full color photographs depict all aspects of childbirth, with line drawings used to explain movement of the baby.
- Covers prenatal care and management of labor. 1991. 144 pages, 341 ills. A Wolfe Medical Publishers, Ltd. title. (Book Code: 06287)

COLOR ATLAS OF LIFE **BEFORE BIRTH: Normal** Fetal Development

Marjorie A. England

- Section I covers overall development of the embryo and fetus and their relationship to the placenta, amnion and chorionic sac.
- Section II provides extensive details on the development of individual organ systems.

1990. 216 pages, 716 ills. with 710 in color. A Wolfe Medical Publishers, Ltd. title. (Book Code: 20326)

Triphasil

Levonorgestrel and ethinyl estradiol tablets— Triphasic regimen 21- and 28-day regimens

SINA MUH U, BECYOSE SHEAT SINKI, MUH THE OCLO

Simple, easy-to-use Day 1 Start

Patient acceptance proven over time

* Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. See prescribing information.

See brief summary on adjacent page.

Worldwide Leadership WYETH-AYERS in Female Healthcare W LABORATORIES Philadelphia, PA 1910

©1991, Wyeth-Averst Laboratories.

Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN SMRT:*

TRIPHASIL* — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol; 17 light-green tablets containing inert ingredients are included in the 28-day regimen)— Triphasic regimen.

Indications and Usage — TRIPHASIL* is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

oral contraceptives (US) as a method of contraception.

Contrainflications — OCs should not be used in women with any of the following: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Endometrial carcinoma or other known or suspected stronger-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contra-ceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

should be strongly advised not to smoke.

Use of OCs is associated with increased risks of serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although risk of serious morbidity/
mortality is very small in heatthy women without underlying risk factors. Morbidity/mortality risk increases
significantly if other risk factors present (i.e. hypertension, hyperlipidemias, obesity, diabetes). Practitioners
prescribing OCs should be familiar with the following information relating to these risks, This information is
based principally on data involving OCs with higher doses of estrogen and progestogen than those commonly
used today. Effect of long-term use of lower estrogen and progestogen formulations is yet to be determined.)

1. Thromboembolic Disorders and Other Vascular Problems — MYDCARDIAL. INFARCTION (M), An increased
risk of MI has been attributed to OC use. Risk is primarily in smokers or women with other underlying risk factors
for coronary-artery disease (i.e. hypertension, hypercholesterolemia, morbid obesity, diabetes). Relative risk of
heart attack for current OC users is estimated to be two to six risk is very low under the age of 30.
Smoking combined with OC use contributes substantially to incidence of MIs in women in their mid-thirties or
older with smoking accounting for majority of excess cases. Mortality rates associated with circulatory disease
increase substantially in smokers over the age of 35 and nonsmokers over the age of 40 among OC users.
OCs may compound effects of well-known insk factors. Such as hypertension, diabetes, hyperlipidemias, age and
obesity in particular some progestogens decrease HDL cholesterol and cause glucose intolerance, while
estrogens may create a state of hyperinsulinism. OCs have been shown to increase blood pressure among users
(see Warnings). Similar effects on risk factors are associated with increased risk of heart disease. Use OCs with
caution in women with cardiovascular diseas

due to OCs is not related to length of use and disappears after pill use is stopped.

A 2- to 4-fold increase in relative risk of postoperative thrombosin or conditions has been reported with OCs. Relative risk of venous thrombosis in women with predisposing conditions is twice that of women without such conditions. If feasible, discontinue OCs at least 4 weeks prior to and for 2 weeks after elective surgery of a type associated with increased risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is associated with an increased thromboembolic isk, start OCs no earlier than 4 to 6 weeks after delivery in women not breast-feeding, or a mid-timester pregnancy termination. CFREBROVASCULAR DISEASES. OCs increase relative and attributable risks of creatrovascular events (thrombotic and hemorrhagic strokes); in general, risk is greatest among older (> 35 years), hypertensive women who smoke, hypertension is a risk factor for users and nonusers, for both types of strokes, while smoking interacts to increase hemorrhagic stroke risk.

DOSE-RELATED RISK OF VASCULAR DISEASE FROM OCS. A positive association has been observed between amount of estrogen and progestogen in OCs and vascular disease isk. A decline in serum high density ilipoproteins (HDL) is reported with many progestational agents. Serum HDL decline is associated with increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, net effect depends on balance archieved between doses of estrogen and progestogen and nature and absolute amount of progestogen regimen prescribed should contain the least amount of estrogen and progestogen compatible with a

The dosage regimen prescribed should contain the least amount of estrogen and progestogen compatible with a low failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of

low failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of estrogen.

PERSISTENCE OF RISK OF VASCULAR DISEASE. Two studies have shown persistence of vascular disease risk for ever-users of OCs. In a U.S. study, Mil risk after OC discontinuation persists for at least 9 years in women 40-49 years who had used OCs for five or more years; increased risk was not demonstrated in other age groups. In a study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after OCs stopped, although excess risk was very small. Both studies used OC formulations with 50 micrograms or higher of estronges.

of estrogens.

2. Estimates of Mortality from Contraceptive Use — A study using data from several sources concluded that with the exception of OC users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The possibility of increased mortality risk with age for OC users is based on data from the 1970s — but reported in 1983. However, current practice involves use of lower estrogen dose formulations combined with careful restriction of OC use to women without the various risk factors listed in this labeling.

the various risk factors listed in this labeling. Changes in practice and new data suggesting that cardiovascular disease risk with OCs may be less than previously observed prompted the Fertility and Maternal Health Drugs Advisory Committee to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with OC use after age 40 in healthy nonsmokers leven with newer low-dose formulations), greater potential health risks are associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if effective, acceptable contraception is not available.

The Committee concluded that the benefits of OC use by healthy nonsmoking women over 40 may outweigh the possible risks. Older women, as all women who take OCs, should use the lowest possible effective dose

formulation.

3. Carcinoma of the Reproductive Organs — Numerous epidemiological studies have looked at the incidence of breast, endometrial, ovarian and cervical cancer in women using OCs, Overwhelming evidence suggests that OC use is not associated with an increase in risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. A few studies show a slightly increased relative risk of developing breast cancer, although the methodology of these studies, including differences in examination of users and nonusers, and in age at start of use, has been questioned.

Some studies suggest that OC use is associated with an increased risk of cervical intraepithelial neoplasia in some populations of women. However, controversy continues about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between OC use and breast and cervical cancers, a cause and effect relationship has not been established.

4. Hepatic Neoplasia—Benign hepatic adenomas are associated with OC use, although incidence is rare in the U.S. Indirect calculations estimate attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

British studies have shown an increased risk of hepatocellular carcinoma in long-term (> 8 years) OC users; these cancers are extremely rare in the U.S. and attributable risk (excess incidence) of liver cancers in OC users approaches less than one per million users.

5. Ocular Lesions — There are clinical case-reports of retinal thrombosis with OC use. Discontinue OCs if there is unexplained partial or complete loss of vision, onset of proptosis or diplopia, papilledema, or retinal vascular lesions; undertake appropriate diagnostic and therapeutic measures immediately.

6. Oral-Contraceptive Use Believe or During Farty Pregnancy—Extensive epidemiological studies revealed no increased risk of birth defects when OCs used prior to pregnancy. Studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. Oc-induced withdrawal bleeding should not be used as a pregnancy test. Do not use OCs during pregnancy to treat threatened or habitual abortion. Rule out pregnancy if two consecutive periods missed before continuing OC use. If patient has not adhered to prescribed schedule, consider pregnancy at time of first missed period. Discontinue OC if pregnancy confirmed.

7. Gallbladder Discase—Earlier studies reported an increased lifetime relative risk of gallbladder surgery in users of OCs and estrogens, more recent studies show that the relative risk of developing gallbladder disease among OC users may be minimal, which may be related to use of formulations with lower hormonal estrogen and progestogen doses.

In Carbonylaride and Lipid Metabolic Effects — OCs cause glucose intolerance in a significant percentage of users. OCs with greater than 75 µg of estrogen cause hyperinsulinism; lower estrogen doses cause less glucos intolerance. Progestogens increase insulin secretion and create insulin resistance (effect varies with different agents). Observe prediabetic and diabetic women carefully while taking OCs. In non-diabetic women, OCs have

no apparent effect on fasting blood glucose.

A small proportion of women will have persistent hypertriglyceridemia while on OCs. Changes in serun triglycerides and lipoprotein levels have been reported in OC users (see Warnings).

regiscences and ipportern levels nave been reported in OC users (see warnings).

9. Elevated Blood Pressure — Increase in blood pressure has been reported in women on OCs, increase is more likely in older OC users and with continued use. Data show that incidence of hypertension increases with increasing quantities of progestogens.

Encourage women with history of hypertension or hypertension-related diseases, or renal disease to use another contraceptive method. Monitor hypertensive women electing to use OCs closely, discontinue OC if significant blood pressure elevation occurs. For most women, elevated blood pressure returns to normal after OC stopped. No difference in occurrence of hypertension among ever- and never-users exists.

Headache — Discontinue OC and evaluate cause at onset or exacerbation of migraine, or if new pattern of

10. Headacene—Discommine U.C. prevision evaluate cause at onset or exacerbation or migraine, or it new pattern of headache (i.e. recurrent, persistent, severel develops.

11. Elevering Irregularities — Breakthrough bleeding and spotting sometimes occur especially during first 3 months of use. Type and dose of progestogen may be important. Consider non-hormonal causes and take adequate diagnostic measures to rule our malignancy or pregnancy in event of breakthrough bleeding, as with any abnormal vaginal bleeding. If pathology excluded, time or a formulation change may solve the problem. In the event of amenometra, rule our pregnancy, Some women encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

Precautions

respectanty when such a contintion was pre-existent.

1. Physical Examination and Follow Up — A complete medical history and physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, conduct appropriate diagnostic measures to rule out malignancy Monitor women with strong lamily history of breast cancer or who have treast nodules with particular care. 2. Lipid Disorders — Follow women being treated for hyperlipidemias closely if they elect to use OCs. Some progestogens may elevate LDL levels and may render control of hyperlipidemias more difficult. (See Warnings) 3. Liver Function — Discontinue OC if jaunctice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. Fluid Retention — OCs may cause some degree of fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions possibly aggravated by fluid retention. 5. Emotional Disorders — if significant depression occurs stop medication and use alternate contraceptive method in attempts to determine if symptom is drug related. Observe carefully those with history of depression and stop drug if depression recurs to serious degree. 6. Contact Lenses — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities are associated with concomitant rifampin use. A similar association though less marked, is suggested with barbiturates, pnerylbutazone, phenylbutazone, phenyl and blood components may be affected by OCs: a Increased prothrombin and factors VII, VIII, X, and X, decreased antithrombin 3: increased noreprephrine-induced platelet aggregability b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), 14 by column or by radioimmunoassay Free T3 resin uptake is decreased, reflecting the elevated TBG, free T3 resin uptake is decreased, reflecting the elevated TBG, free T3 resin uptake is decreased, reflecting the elevated TBG, free T3 resin uptake is decreased. reflecting the elevated TBG, free T3 resin uptake is decreased. reflecting the elevated TBG, free T3 resin uptake is decreased. In Calcose to the case of the concentration of the contraction of the contr

Information for the Patient — See Patient Package Labeling.

Adverse Reactions — An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, arreial thromboembolism; pulmonary embolism; myocardial infarction; cerebral hemorrhage; cerebral thrombosis; hypertension, gallbladder disease; hepatic adenomas or benign

There is evidence of an association between the following conditions and OC use, although additional confirmatory studies are needed: mesenteric thrombosis; retinal thrombosis.

There is evidence of an association between the following conditions and OC use, although additional confirmatory studies are needed mesenteric thrombosis; retinal thrombosis; retinal thrombosis; studies are needed mesenteric thrombosis; retinal thrombosis; retinal thrombosis; studies are needed mesenteric thrombosis; retinal thrombosis; retinal thrombosis; studies are believed to be drug-related nausea; vornifing, gastrointestinal symptoms (such as abdominal campas and bloating); breakthrough bleeding; spotting; change in mensitual flow, amenorinea; temporary intertility after treatment discontinued; edema: melasma which may persist; breast changes tendemess, enlargement, secretion; change in weight (increase or decrease); change in mensitual ensoin and secretion; diminitudin in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidassis, change in corneal curvature (steepering); intolerance to contact tenses.

The following adverser exactions have been reported in OC users and the association is neither confirmed nor refuted; congenital anomalies; premenstrual syndrome, cataracts; optic neuritis; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hissuitism; loss of scalp hair, eythema multiforme; eythema nodosum; hemorrhagic eruption; vaginitis; porphyria; impaired renal function, hemolytic uremic syndrome; budd-Chari syndrome; ache; changes in libido; collis; sickle-cell disease; cerebral-vascular disease with mitral valve prolasse; hypus-like syndromes.

Overdosage — Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nause, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits — The following noncontraceptive health benefits related to OC use are supported by epidemiological studies that largely utilized OC formulations containing doses exceeding 0.035 mg of ethingle

Dosage and Administration — For maximum contraceptive effectiveness, take TRIPHASIL* (levonorgestrel and ethinyl estradiol tablets — triphasic regimen 21- and 28-day regimens) exactly as directed and at intervals not over 24 hours.

(If TRIPHASIL.* is first taken later than first day of first menstrual cycle of medication or postpartum, contra-ceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.) For full details on dosage and administration see prescribing information in package insert.

Count on EFOTAN[®]IM/IV (cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE

Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Treat_Infections_caused by F.ord. // kebsiella species (including // pneumoniae), Proteus mirabilis, and Proteus sp (which may include the organisms now called Proteus vulgaris, Providencia content, and Monagorella morecarii).

mirabilis, and Proteuts sp (which may include the organisms flow called Proteus Volgans, Providenta, rettgeri, and Morganella morganii).

Lower Respiratory Tract Infections caused by Streptococcus pneumoniae (formerly D pneumoniae) Staphylococcus aureus (penicillinase- and nonpenicillinase- producing strains), Haemophilus influen (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus

Staphylococcus aireus (pericillinase- and nonpenicillinase-producing strains), Haemophilus influenzae (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus mirabilis, and Serratia marcescens:

Skin and Skin Structure Infections caused by Staphylococcus aureus (penicillinase- and nonpenicillinase-producing strains), Staphylococcus epidermidis, Streptococcus progenes, Streptococcus species (excluding enterococci), E coli, Klebsiella pneumoniae, and Peptococcus and Peptostreptococcus species (excluding enterococci), E coli, Klebsiella peneumoniae, and Peptococcus and Peptostreptococcus species (excluding penicillinase-producing strains), Staphylococcus epidermidis, Streptococcus species (excluding enterococci), group B streptococcus and Peptostreptococcus species) and B thetaiotaomicron, Flobacterium species, and gram-positive anaerobic cocci (including Peptococcus and Peptostreptococcus species).

Intra-abdominal Infections caused by E coli, Klebsiella species (including K pneumoniae), Streptococcus species (excluding enterococci), Bacteroides species (excluding B distasonis, B ovatus, and B thetaiotaomicron), and Clostridium species.*

Bone and Joint Infections caused by Staphylococcus aureus.*

Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known, however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Detote the aminoglycoside are used concomitantly with an aminoglycoside bacteria. The dosage recomm

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics. WARNINGS

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoletan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures. Pseudomembranous colitists has been reported with the use of cephalosporins (and other broadspectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by Clostridium difficile is one primary cause of antibiotic associated colitis.

biotic-associated colitis

antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by C difficile. Other causes should also be considered. In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated. PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested

flushing, sweating, headache, and tackycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an appropriate process.

Drug/Laboratory Test Interactions: A false positive reaction for glucose in urine may occur with Benedicts or Fehling's solution.

As with other cephalosporins, high concentrations of celotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of

creatinine reported.

Carcinogenesis, Mutagenesis, impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of

500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylintotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Usage In Pregnancy: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE FRACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

ADVENSE REAGINANS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy,
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and

Gastrointestinal symptoms occurred in 1.3% or patients, the most request that distinct characters are marked (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching the results of the state of the stat

(1 in 700).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hemolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembranous colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION

Treatment: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intra-muscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be deter-mined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN			
Type of Infection	Daily Dose	Frequency and Route	
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM	
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM	
Severe	4 grams	2 g every 12 hours IV	
Life-Threatening	6* grams	3 a every 12 hours IV	

^{*}Maximum daily dosage should not exceed 6 grams.

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION			
mL/min	Dose	Frequency	
>30	Usual Recommended Dosage*	Every 12 hours	
10-30	Usual Recommended Dosage*	Every 24 hours	
<10	Usual Recommended Dosage*	Every 48 hours	

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min. When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

Weight (kg) × (140 - age) Males 72 × serum creatinine (mg/100 mL)

Females:

 $0.9 \times \text{value for males}$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

Spontaneous preterm birth: A case-control study

1290

Ine de Haas, MD, Bernard L. Harlow, PhD, Daniel W. Cramer, MD, ScD, and Fredric D. Frigoletto, Jr., MD Boston, Massachusetts

Demographic characteristics and the influence of smoking, weight, reproductive history, and maternal diethylstilbestrol exposure were evaluated with respect to the risk of spontaneous preterm delivery.

An extraordinarily high CA 125 level in a woman without apparent pathologic foci of CA 125 production: Dissociation between serum levels of CA 125 and CA 130

1297

Fuminori Kobayashi, MD, Shingo Fujii, MD, Hirofumi Nonogaki, MD, Yoshihiko Nanbu, MD, Toshiko Iwai, MD, Ikuo Konishi, MD, Norimasa Sagawa, MD, Takahide Mori, MD, Masako N. Hosono, MD, and Keigo Endo, MD

Kyoto, Japan

A case of extraordinarily high serum levels of CA 125 without the apparent pathologic foci of CA 125 production is presented.

Severe obstructive sleep apnea and associated snoring documented during external tocography

1300

David M. Sherer, MD, Christine B. Caverly, RN, and Jacques S. Abramowicz, MD Rochester, New York

Snoring after apneic episodes documented by external tocography in the third trimester subsequently led to diagnosis of severe obstructive sleep apnea.

Management of fetal hemolytic disease by cordocentesis. II. Outcome of treatment

1302

Carl P. Weiner, MD, Roger A. Williamson, MD, Katharine D. Wenstrom, MD, Susan L. Sipes, MD, John A. Widness, MD, Stanley S. Grant, RN, and Louise Estle, RN *Iowa City, Iowa*

Simple intravascular fetal transfusion safely suppresses fetal erythropoiesis and allows term delivery.

Lack of an association between late fetal death and antiphospholipid antibody measurements in the second trimester

1308

James E. Haddow, MD, Neal S. Rote, PhD, Dorene Dostal-Johnson, MS, Glenn E. Palomaki, BS, Andrea J. Pulkkinen, MS, and George J. Knight, PhD Scarborough, Maine

Antiphospholipid antibody measurements obtained at ≥ 15 weeks' gestation are not helpful in identifying pregnancies at risk for fetal death.

(Contents continued on page 11A)

Cord Blood pH...adding objectivity the newborn assessment.

Corometrics 220 pH System provides a simple, immediate and objective means of obtaining cord blo

Umbilical cord blood sampling provides a reliable measurement for objectively ing the presence or extent of fetal asphyxia at delivery. Assessment of cord blood j is indicated when ominous electronic fetal heart rate patterns are present, when oth intrapartum distress are observed, or when unsuspected neonatal distress is noted. In conjunction with traditional APGAR scoring methods and the assessment of fetal patterns, cord blood pH can serve as a more precise indicator of newborn status after as compared to any single assessment method. Cord blood pH values can also retrospectively evaluate intrapartum labor management practices.

The Corometrics 220 pH System is recognized by many to be the simplest, n means of obtaining important arterial and venous cord blood pH values.

- A section of the umbilical cord is double-clamped at delivery.
 - The disposable pH cartridge is inserted into the 220 pH monitor.
 - A 15 μl cord blood sample is collected and inserted into the monitor. The precise pH value is displayed within 15 seconds!

The Corometrics 220 pH System allows for quick an

Severe ovarian hyperstimulation in a spontaneous singleton pregnancy

1312

Gregory F. Rosen, MD, MS, and Mitchell W. Lew, MD

Irvine and Long Beach, California

Severe ovarian hyperstimulation syndrome accompanying a spontaneous but otherwise normal singleton pregnancy is reported.

Pseudoprognathism—An auxiliary ultrasonographic sign for transvaginal ultrasonographic diagnosis of cleft lip and palate in the early second trimester

1314

M. Bronshtein, MD, N. Mashiah, MD, I. Blumenfeld, DMD, and Z. Blumenfeld, MD Haifa, Israel

Transvaginal ultrasonographic examination was helpful in correctly diagnosing three cases of cleft lip, by means of the pseudoprognathism sign on sagittal paramedial section of the fetal face.

Extended longitudinal study of uterine activity among low-risk women

1317

Denise M. Main, MD, Jeane A. Grisso, MD, Tiazu Wold, BA, Ellen Sim Snyder, MS, John Holmes, MS, and Grace Chiu, PhD

Philadelphia, Pennsylvania

This study demonstrates a significant association between prelabor contraction frequency and gestational age, time of day, and maternal weight.

Videolaseroscopy for oophorectomy

1323

Farr Nezhat, MD, Camran Nezhat, MD, and Sheryl L. Silfen, MD Atlanta, Georgia

Videolaseroscopic oophorectomy is a safe alternative to laparotomy for certain cases of removal of the ovaries.

Inappropriate secretion of antidiuretic hormone in Sheehan's syndrome: A rare cause of postpartum hyponatremia

1330

Chaim Putterman, MD, Yaniv Almog, MD, Yoseph Caraco, MD, David J. Gross, MD, and Eldad Ben-Chetrit, MD

Jerusalem, Israel

A patient with inappropriate antidiuretic hormone secretion and severe hyponatremia as the initial manifestation of early Sheehan's syndrome is described.

Congenital heart block: Successful prophylactic treatment with intravenous gamma globulin and corticosteroid therapy

1333

Risto Kaaja, MD, Heikki Julkunen, MD, Pirkko Ämmälä, MD, Anna-Maija Teppo, MSc, and Pekka Kurki, MD Helsinki, Finland

A mother with anti-Ro antibodies whose previous pregnancy ended in delivery of a child with congenital heart block was successfully treated with intravenous gamma globulin and corticosteroids.

(Contents continued on page 13A)

To be continued...

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm

- □ Easy to insert and position
- □ Easy to clean and maintain
- □ Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
- ☐ The combination for continuation—with 4 out of 5 patients continuing after 1 year[†]

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Ortho ALL-FLEX* D I A P H R A G M

†Number of patients continuing the method for 12 consecutive months; data on file, Ortho Pharmaceutical Corporation.

‡Data on file, Ortho Pharmaceutical Corporation. Consult the patient brochure for information on toxic shock syndrome (TSS) and wearing time.

Amniotic fluid contains tissue factor, a potent initiator of coagulation

1335

Charles J. Lockwood, MD, Ronald Bach, PhD, Arabinda Guha, PhD, Xiaodong Zhou, MD,

Wayne A. Miller, MD, and Yale Nemerson, MD

New York, New York, and Lexington, Massachusetts

Amniotic fluid contains high concentrations of intact, partially active tissue factor, which increase with gestational age and account for the procoagulant property of amniotic fluid.

Laser vaporization of grade 3 vaginal intraepithelial neoplasia

1342

Mitchel S. Hoffman, MD, William S. Roberts, MD, James P. LaPolla, MD, James V. Fiorica, MD, and Denis Cavanagh, MD

Tampa, Florida

Laser vaporization was not efficacious treatment for grade 3 vaginal intraepithelial neoplasia diagnosed in the region of a vaginal cuff scar.

On reducing the frequency of severe abruptio placentae

1345

Jack A. Pritchard, MD, F. Gary Cunningham, MD, Signe A. Pritchard, RN, and Ruble A. Mason, RMT Dallas, Texas

The elimination of very high parity and the influx of large numbers of Latin American patients decreased the incidence of severe abruptio placentae by one half.

A rapid visual test for predicting fetal lung maturity

1351

Anthony J. Sbarra, PhD, Anjan Chaudhury, MD, Curtis L. Cetrulo, MD, Robert Mittendorf, MD, Chris Shakr, MD, Robert Kennison, MD, Johannes Jones, MD, and Joseph Kennedy, Jr., MD Boston, Massachusetts

A rapid bedside test that predicts when the usual indices for fetal pulmonary maturity will be positive or negative is proposed.

Fetal abdominoscrotal hydrocele

1353

P. Sasidharan, MD, Stanley Crankson, MB, and Saeed Ahmed, MB Riyadh, Saudi Arabia

Antenatal ultrasonography detected a fetal intraabdominal cyst that was an abdominoscrotal hydrocele, the neonatal diagnosis and management of which are described.

Increased serum levels of macrophage colony-stimulating factor in ovarian cancer

1356

F.-J. Xu, MD, S. Ramakrishnan, PhD, L. Daly, J.T. Soper, MD, A. Berchuck, MD, D. Clarke-Pearson, MD, and R.C. Bast, Jr., MD

Durham, North Carolina, and Minneapolis, Minnesota

Elevated serum levels of macrophage colony-stimulating factor that were observed in ovarian cancer in the absence of concomitant serum CA 125 elevation indicate its value as a complementary tumor marker.

Postpartum preeclampsia-induced shock and death: A report of three cases

1362

Jerome S. Kalur, JD, James N. Martin, Jr., MD, Kent A. Kirchner, MD, and John C. Morrison, MD Cleveland, Ohio, and Jackson, Mississippi

A rare complication of preeclampsia is sudden severe hypotension followed by hyponatremia and death.

Renal agenesis in association with malformation of the female genital tract

1368

Pedro Acién, MD, José A. Ruiz, MD, José F. Hernandez, MD, Francisco Susarte, MD, and Angel Martin del Moral, MD

Alicante, Spain

Renal agenesis is associated with ipsilateral blind vagina or agenesis of all organs derived from the urogenital ridge.

The association between fetal karyotype and mean corpuscular volume

1371

Susan L. Sipes, MD, Carl P. Weiner, MD, Katharine D. Wenstrom, MD, Roger A. Williamson, MD, and Stanley S. Grant, RN

Iowa City, Iowa

An elevated fetal mean corpuscular volume may be an indication for karyotypic evaluation.

Cytologic localization of epidermal growth factor and its receptor in developing human placenta varies over the course of pregnancy

1377

Cecilia A. Ladines-Llave, MD, Takeshi Maruo, MD, Augusto S. Manalo, MD, and Matsuto Mochizuki, MD Kobe, Japan, and Manila, Philippines

Cytologic localization of epidermal growth factor and its receptor in developing human placenta varies over the course of pregnancy, in association with the demands of fetoplacental development.

Case report of myocardial infarction in labor

1383

Nicole E. Menegakis, MD, and Marvin S. Amstey, MD Rochester, New York

A 37-year-old woman, who had normal coronary arteries, had a myocardial infarction attributed to smoking and Pitocin while in labor.

Endocrine effects in female weight lifters who self-administer testosterone and anabolic steroids

1385

William B. Malarkey, MD, Richard H. Strauss, MD, Daniel J. Leizman, MD, Mariah Liggett, PhD, and Laurence M. Demers, PhD

Columbus, Ohio, and Hershey, Pennsylvania

Multiple endocrine alterations are caused by anabolic steroid use in women weight lifters, and some of these alterations may increase the risk of premature atherosclerosis.

Bleeding after intravascular transfusion: Experimental and clinical observations	1414
M. Segal, BSc, F.A. Manning, MD, C.R. Harman, MD, and S. Menticoglou, MD Winnipeg, Manitoba, Canada	
Postpuncture umbilical vessel bleeding varies by cord perfusion rate, needle size, vessel punctured, and fetal platelet count.	
Recombinant 8 syndrome: The pool of Hispanic pericentric inversion 8 carriers expands numerically and geographically Luis A. Izquierdo, MD, Thomas S. McConnell, MD, Luis B. Curet, MD, and Gloria E. Sarto, MD, PhD Albuquerque, New Mexico	1419
The number of persons at risk for recombinant 8 syndrome may be higher than previously considered and will soon no longer be confined to the southwestern United States.	
Subchorionic hematomas and the presence of autoantibodies Laxmi V. Baxi, MD, and Melissa M. Pearlstone, MD New York, New York	1423
An association of autoantibodies in five patients with subchorionic hematomas is described.	
The dimension of chaos in the fetal heart rate David G. Chaffin, MD, Cynthia C. Goldberg, MSIV, and Kathryn L. Reed, MD Tucson, Arizona	1425
"Chaos" as the origin of fetal heart rate variability is explored with the nonlinear technique of dimensional analysis of phase-space attractors.	
Identifying pregnant women who drink alcoholic beverages Patricia Dolan Mullen, DrPH, Joseph P. Carbonari, EdD, and Marianna C. Glenday, MPH Houston, Texas	1429
Comparison of questions to elicit information regarding use of alcohol at entry into prenatal care indicates that a written multiple choice question improves disclosure over the ususal "yes or no" format in written or oral form.	
Human papillomavirus infection in women with multicentric squamous cell neoplasia	1431
Anna Marie Beckmann, PhD, Randy Acker, MS, Audrey E. Christiansen, BS, and Karen J. Sherman, Ph. Seattle, Washington	D
Human papillomavirus deoxyribonucleic acid was detected in invasive cancers or grade 3 intraepithelial neoplasia tissues in 32 women with multicentric squamous cell neoplasia.	

Contents

Human T-cell lymphotropic virus type I infection and pregnancy: A case-control study and 12-month follow-up of 135 women and their infants

1438

Yves Ville, MD, Eric Delaporte, MD, Martine Peeters, PhD, Marianne Leruez, MD, Eric Glowaczower, MD, and Hervé Fernandez, MD

Franceville, Gabon, and Clamart and Paris, France

The interaction between human T-cell lymphotropic virus type I seropositivity and the course and outcome of pregnancy was analyzed in a case-control study; the means of transmission of the virus in Gabon are discussed.

Detection of *Chlamydia trachomatis* endocervical infection in asymptomatic and symptomatic women: Comparison of deoxyribonucleic acid probe test with tissue culture

1444

Lisa I. Yang, MD, Elizabeth S. Panke, MD, PhD, Phyllis A. Leist, PhD, Richard J. Fry, MD, and Richard F. Lee, PhD

Cincinnati. Ohio

The deoxyribonucleic acid probe test (PACE 2, Gen-Probe, San Diego) is equivalent to standard tissue culture in sensitivity, specificity, and positive and negative predictive values.

Loxoscelism threatening pregnancy: Five cases

1454

Philip C. Anderson, MD Columbia, Missouri

Bites of the most poisonous North American spider, Loxosceles reclusa, during pregnancy seem to cause no unusual risks to the fetus in this (first) report of five cases.

Failure to verify high activities of polyamine oxidase in pregnancy serum

1457

Takeshi Kumazawa, MS, Osamu Suzuki, MD, Hiroshi Seno, MD, Shigehiko Mizutani, MD, and Takatoshi Matsumoto, MD

Hamamatsu and Nagoya, Japan

Polyamine oxidase activity in pregnancy serum was steady at very low levels and not higher than that in nonpregnancy serum.

BASIC SCIENCE SECTION

Amnioinfusion increases amniotic pressure in pregnant sheep but does not alter fetal acid-base status

1459

Nicholas M. Fisk, MB, Dino A. Giussani, BSc, Michael J. Parkes, DPhil, Peter J. Moore, PhD, and Mark A. Hanson, DPhil

Reading, Berkshire, United Kingdom

Amnioinfusion of 5 to 15 L in seven ewes increased amniotic pressure but produced no change in mean fetal pH, PCO₂, PO₂, arterial pressure, or heart rate.

A forward shift in the initiation of the nocturnal estradiol surge results in a daily 3- to 5-hour period of elevated estradiol/progesterone ratio.	
Measurement of human epidermal growth factor receptor in the endometrium during the menstrual cycle Vladimir Troche MD, Dennis M, O'Connor MD, and R, Burl School C, DED	99
Vladimir Troche, MD, Dennis M. O'Connor, MD, and R. Paul Schaudies, PhD Washington, D.C., and Bethesda, Maryland	
The endometrial epidermal growth factor receptor content is cycle dependent, being maximal during the periovulatory period and minimal just before, during, or after menses.	

Contents

Fetal cardiovascular and fluid responses to maternal volume loading with lactated Ringer's or hypotonic solution

1504

David R. Powers, MD, and Robert A. Brace, PhD San Diego, California

Acute reductions in maternal osmolality appear to promote fluid transfer to the ovine fetus but volume-induced increases in maternal vascular pressures do not.

Oxytocin secretion and human parturition: Pulse frequency and duration increase during spontaneous labor in women

1515

Anna-Riitta Fuchs, DSc, Roberto Romero, MD, David Keefe, MD, Manuel Parra, MD, Enrique Oyarzun, MD, and Ernesto Behnke, MD

New York, New York, New Haven, Connecticut, and Santiago, Chile

In parturient women oxytocin is secreted in discrete pulses, the frequency and duration of which are significantly increased in the first, second, and third stages of spontaneous labor.

Dose-dependent effects of angiotensin II on the ovine fetal cardiovascular system

1524

Oliver W. Jones III, MD, Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD San Diego, California

Angiotensin II affects ovine fetal arterial pressure, venous pressure, heart rate, and blood volume in a dose-dependent manner, suggesting that angiotensin II is an important regulator of the entire fetal cardiovascular system.

In vivo and in vitro effects of magnesium sulfate in the cerebrovascular bed of the goat

1534

Alfredo J. Perales, MD, Germán Torregrosa, PhD, Juan B. Salom, PhD, Francisco J. Miranda, MD, José A. Alabadí, BSc, Javier Monleón, MD, and Enrique Alborch, MD *Valencia, Spain*

Magnesium sulfate injected directly into the cerebral circulation or infused intravenously increases cerebral blood flow in conscious nonpregnant goats and relaxes isolated goat middle cerebral arteries.

The ability of recombinant tissue plasminogen activator to inhibit post-radical pelvic surgery adhesions in the dog model

1539

F.J. Montz, MD, J. McCabe Fowler, MD, A. John Wolff, BS, Silas M. Lacey, and Margie Mohler, PhD Los Angeles, California

Intraperitoneal recombinant tissue plasminogen activator was effective at preventing post-radical pelvic surgery adhesions in a canine model.

Effects of magnesium and terbutaline on contractility and K⁺ uptake in isolated human uterine muscle

1543

Kristjar Skajaa, MD, Maria E. Everts, PhD, Torben Clausen, MD, PhD, and Axel Forman, MD, PhD Aarhus. Denmark

Therapeutic concentrations of Mg⁺⁺ and terbutaline effectively inhibited contractions in isolated human pregnant myometrium by mechanisms independent of the Na⁺-K⁺ pump.

Fungal morphology after treatment with itraconazole as a single oral dose in experimental vaginal candidosis in rats

1552

Tine M. Jansen, DVM, Marie-Anne A. Van de Ven, Marcel J. Borgers, PhD, Frank C. Odds, PhD, and Jan M.P. Van Cutsem

Beerse, Belgium

The fast and prolonged antifungal action of a single oral dose of itraconazole is illustrated at the structural level with the use of light microscopy and with transmission and scanning electron microscopy.

Role of endogenous atrial natriuretic factor in the regulation of fetal cardiovascular and renal function

1558

Cecilia Y. Cheung, PhD La Jolla, California

Reduction of plasma atrial natriuretic factor concentration by immunoneutralization in the ovine fetus resulted in a transient hypotension followed by a mild hypertension, accompanied by a significant decrease in urine flow rate.

A rabbit model for bacterially induced preterm pregnancy loss: Intervention studies with ampicillin-sulbactam

1568

Robert S. McDuffie, Jr., MD, Sandra J. Blanton, MS, Robert H. Shikes, MD, and Ronald S. Gibbs, MD Denver, Colorado

When pregnant rabbits at 70% gestation were inoculated hysteroscopically with *Escherichia* coli, treatment with ampicillin-sulbactam resulted in significantly less pregnancy loss than no treatment.

Editors' note

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case report, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

The JOURNAL is abstracted and/or indexed in Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague, and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby-Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. She needs PREMARIN to help prevent further bone loss

Calcium¹ and exercise are not enough to prevent postmenopausal osteoporosis, since estrogen deficiency is the primary cause.² PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.³

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.4

PREMARIN°

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogendependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN (conjugated estrogens tablets)

0.3 mg 0.625 mg

For atrophic vaginitis

PREMARIN (conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)

PREMARIN® Brand of conjugated estrogens tablets, USP PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that natural "estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses. 2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female tetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares urine It contains estrone, equilin, and 17a-dihydroequilin, together with smaller amounts of 17a-estradies equilenin, and 17a-dihydroequilenin as salts of their sulfate seters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated

estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism,

castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and

PREMARIN (conjugated estrogens) vaginar cream is more accounted by valvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions:

1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogenent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thrombophlebitis of thrombophlebitis and thrombophlebitis and thrombophlebitis and thrombophlebitis and thrombophlebitis disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below).

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophtebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose. Blood pressure should be monitored with estrogen use, especially it high doses are used. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion for progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects on examination and a complete medical and family history should be taken prior to the initiation of any

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should

include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dystunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine lelomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (rotal contraceptives):

combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-

1. Increased prointmonia and actors vii, viii, X, and X, decreased antitriumbun 3, increased interprine induced platelet aggregability.
 2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T₄ levels determined by column or by radioimmunoassay. Free T₃ resin uptake is decreased, reflecting the elevated TBG; free T₄ concentration is unaltered.
 3. Impaired glucose tolerance.
 4. Reduced response to metyrapone test.
 5. Reduced serum folder concentration.

5. Reduced serum totate concentration. MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See CONTRAINDICATIONS and Paved Warning.

PRESHANCY CATEGORY X: Estrogens should not be used during pregnancy. See CONTRAINDICATIONS and Boxed Warning MUTSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine libromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erytherma multiforme, erytherma nodosum, hemorrhagic eruption, loss of scalp hair, histuitism; stepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. Given cyclically for short-term use only. For treatment of moderate-to-severe vasomotor symptoms, alrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be made at three- to six-month intervals.

2. Given cyclically: Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis.—0.625 mg daily. Administration should be exclic feet, three weeks on and one week off).

Osteoporosis.—0.625 mg daily. Administration should be cyclic (eg. three weeks on and one week off).

PREMARIN* Brand of conjugated estrogens Vaginal Cream
Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as

In the lowest use with control symptoms anothe be made at three- to six-month intervals.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an infact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Invariant Performance Reconstruction...

The GORE-TEX Surgical Membrane— Configured for Peritoneal Reconstruction protects denuded areas while healing progresses beneath the material.

n Peritoneal

...The GORE-TEX® Surgical Membrane The Choice in Peritoneal Reconstruction

Successful peritoneal reconstruction following pelvic surgery in the female requires dependable measures to establish the continuity of the peritoneum and the normal anatomy of the pelvic area.

Medical literature reports the use of an inert, nonabsorbable barrier as an attractive means of approaching this goal.

Performance by Design

Composed of the inert biomaterial expanded polytetrafluoroethylene (e-PTFE), the GORE-TEX Surgical Membrane limits tissue attachment with an extremely small pore size (<1µ). The nonabsorbable GORE-TEX Surgical Membrane is a physical barrier that remains in place to protect denuded areas as healing is completed, unlike absorbable materials, which provide a limited time of protection.

The GORE-TEX Surgical Membrane has a long record of safety and effectiveness. It has demonstrated reliability among cardiac surgeons for more than 14 years. addition, use in multicenter clinical studies continues to substantiate safety and the invariant performance of the GORE-TEX Surgical Membrane

Convenient

Available in specific configurations tailored for peritoneal reconstruction; the GORE-TEX Surgical Membrane — *Configured for Peritoneal Reconstruction* — is packaged sterile and **can be resterilized**.

Choose the GORE-TEX Surgical Membrane for invariant performance in peritoneal reconstruction. To receive further information or to consult with an application specialist, call 800-437-8181. For orders and overnight delivery 24 hours a day, call 800-528-8763.

INFORMATION FOR AUTHORS Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

- Dr. Zuspan—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.
- Dr. Quilligan—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval before the experiment is started and approval must be so indicated in the Material and Methods section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must state in the Material and Methods section of the manuscript that the guidelines for the care and use of the animals approved by the local institution were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and Material and Methods section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22×28 cm ($8\frac{1}{2} \times 11$ inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic

degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 key words or short phrases for indexing purposes.

A structured abstract is required for certain types of articles and a standard abstract format is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: Objective(s); Study Design; Results; and Conclusion(s). The Objective(s) reflects the purpose of the study, that is, the hypothesis that is being tested. The Study Design should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The Results include the outcome of the study and statistical significance if appropriate. The Conclusion(s) states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's Manual of Style. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the Material and Methods section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the Results section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles

should conform to abbreviations used in Cumulated Index Medicus.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term figure includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For black-and-white figures, submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For color figures submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted unmounted with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. Color figures are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computergenerated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include standard abstract format, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title.

If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract must follow the structured format.

Clinical Opinion. Limit of 3000 words. Include standard abstract format of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include standard abstract format of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of \$60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby—Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms must be completed and sent with each submitted manuscript. If not completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

- —The original and two copies of the manuscript are submitted.
- —The completed checklist is enclosed. The assignment of copyright signed by all authors accompanies the manuscript.
- —Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
- —Guidelines for the care and use of nonhuman animals or other species approved by the institution have been followed as indicated in the Material and Methods section. The species is named in the title, abstract, key words, and Material and Methods section.
- —The covering letter with essential information is with the manuscript.
- —All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
- —All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
- —Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
- —Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

- Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
- -Similarities, differences and explanation are provided in

the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

- -These elements are given in the following sequence, and are typed double-spaced.
- -Title.
- —Author(s) name(s) and highest academic degree(s) are shown.
- —City(ies), state(s), and country other than United States in which the study was conducted are given.
- —The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
- -Acknowledgment of financial support is cited.
- —Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
- —If reprints will not be available, this has been stated on the title page.
- —If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
- —At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

- -The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
- —A structured abstract, with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
- —A standard abstract is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

- -Are typed double-spaced.
- —Are numbered consecutively in the order they are cited in the text.
- —The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
- —Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

- —Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
- —Three sets of unmounted glossy prints for black-andwhite figures are submitted, properly numbered, labeled, and top indicated on the back of each print.

- —Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
- —Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

- -Are provided for each figure.
- —Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

- —Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
- -Tables are cited in numeric sequence in the text.

Premier Nedicine, N

In the Pregnant Patient + Medical Disorder equation, where do you fit in?

A pregnant patient with a medical disorder poses a unique and special challenge. You need to understand her disease and how it affects her pregnancy. You also need to recognize the physiologic signs of a normal gestation in order to best treat her overall condition.

In this premier volume of **Current Obstetric Medicine**, international authorities discuss recent developments in obstetric medicine, summarizing pertinent findings and trends from the literature published within the last two years. They also add their own critical commentary, providing new perspectives on the problems you face. Concentrating on emerging treatments and insights, the authorities focus on how these innovations affect your patients and your practice. This combination of the latest research and expert interpretation makes **Current Obstetric Medicine**, **Volume 1** a vital clinical reference.

You'll get a multidisciplinary perspective of new diagnostic techniques and therapies, such as preconception counseling and management of asthma, rhinitis, and anaphylaxis during pregnancy. A wide spectrum of conditions and problems are covered, including renal disease, postpartum thyroiditis, diabetes, and accidents. And each issue in **Current Obstetric Medicine** is discussed in terms of its clinical significance—so you can start applying the best available treatments to your patients' care immediately.

To review this outstanding resource free for 30 days, simply mail the Free Examination Certificate below or call Toll-Free 1-800-426-4545 (To speed your order, mention code "MCA-029"). If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It's an easy way to place yourself in the patient care equation.

FREE EXAMINATION CERTIFICATE Please send me Current Obstetric Medicine, Volume 1 (21178). I understand that I will pay \$59.95* plus shipping and handling if I decide to keep the book. * Resident price \$40 NAME ADDRESS CITY/STATE/ZIP TELEPHONE Mosby Year Book Pat Newman 11830 Westline Industrial Drive St. Louis, MO 63146 MCA-029

When you purchase, we'll send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you do not want the Current, the advance notice makes it easy for you to let us know. And if you elect to receive the new Current, you need do nothing. We will send it on publication. No worry. No wasted motion. "Comprehensive Gynecology is just that." (The Journal of Family Practice, review of first edition.)

New 2nd Edition!

COMPREHENSIVE GYNECOLOGY

Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; Morton A. Stenchever, M.D.; and William Droegemueller, M.D.

The broad scope of this authoritative text covers the most recent advances in the field for residents and practitioners.

- Each chapter begins with a list of key terms and definitions and ends with a list of key points.
- Features increased coverage of perimenopausal and postmenopausal topics and improved coverage of dysfunctional uterine bleeding.

December 1991. Approx. 1,184 pages, 129 ills. (Book Code: 06244)

Also available: COMPREHENSIVE GYNECOLOGY REVIEW, 2nd Edition

by Holzman, et al. A perfect supplement for Residents preparing for the boards.

A red spot means a lot to a woman. A red spot may mean breakthrough bleeding.

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting®

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles¹

n = number of women with a bleeding event occurring during a cycle.

TRILEVIEN Levonorgestrel and ethinyl estradiol tablets - Triphasic regimen may mean a lot to a woman

- * Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives.

 The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.
- † Defined as intermenstrual bleeding.

TRI-LEVLEN® Levonorgestrel and ethinyl estradiol tablets-Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

11-Leviens— B brown tobiets, each containing 0.050 mg of levonorigestrel (dc'-)-13 beta-ethyl-17-olipha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17a-pregna-1.3,5(0)-tinen-20-yne3,17 diot), 5 white tablets, each containing 0.075 mg levonorigestrel and 0.040 mg ethinyl estradiol. (0 light-yellow tablets,
each containing 0.125 mg levonorigestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are
included in the 28-day triphasic regimen).

inclinations and Usage
Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

ntraindications

Contamactions
Oral confraceptives should not be used in women with any of the following conditions: thrombophiebits or thromboembolic disorders, a past history of deep-ven thrombophiebits or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected corcinoma of the breast, carcinoma of the endometrium or other known or suspected estragendependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic joundice of pregnancy or joundice with prior use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

who use oral confraceptives should be strongly acrived not to smoke.

The use of oral confraceptives as associated with increased risks of several senious conditions including myocardial infarction, thromboembolism, stroke, hepotic neoplasia, galiblodder disease, and hypertension, although the risk of senious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and morbidity increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemics, obesity and diabetes Practitioners prescribing oral confraceptives should be familiar with the following information relating to these risk indistriction contained in this package insert is principally based on studies corried out in patients who used oral confraceptives with higher formulations of estragens and progestagens than those in common use today. The effect of long-fermuse of roal confraceptives with lower formulations of both estragens and progestagens remains to be determined. Throughout this labeling, epidemiological studies provide are of two hypes: retrospective or case control studies and prospective or cohort studies accurate and the provide information on the actual clinical occurrence of a disease of measure of the relative risk does not provide information on the actual clinical occurrence of a disease control studies provide in a control of the provide information. For further information, the reader is referred to a text on epidemiological methods.

1. **Innomboembolic Disorders and Other Vascular Problems**

in the population. For further information, the reader is referred to a fext on epidemiological methods.

1. Thromboembolic Disorders and Other Vascular Problems
a. Myccardial Infanction. An increased risk of myccardial infanction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hyper-cholesterolemial, morbid obesity, and diabetes. The relative risk of heart dirack for current oral-contraceptive use has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infanctions in women in their mid-finities or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives or oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyper-lipidemias, age and obesity. In particular, some progestagens are known to decrease HDL cholesterol and cause glucose infolerance, while estingens may create a state of hyperimalunism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heard disease oral contraceptives must be used with coution in women with cordiovascular disease isk factors.

Introducerous and the subsequent of the propertion of an attendance of several calendary and an advanced and thromboembolic and thromboembolic and thromboembolic and thromboembolic and thromboembolic and thromboembolic and thromboembolic and thromboembolic and thromboembolic and

risk of heard disease. Oral contraceptives must be used with coution in women with caralovascular disease risk factors.
Intromberabolism. An increased risk of thromboembolic and thrombotic disease associated with the so of oral confraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thiombosis. 4 to 11 for deep vein intrombosis or pulmonary embolism, and 1 5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4 5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of enous histority or women who have predisposing conditions is tivice that of women without such medical conditions. If feasible, and confraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, and contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

should be started no earlier than four to six weeks after delivery in women who elect not to breast-teed, or a midtrimester pregnancy termination.

Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is gredest among older (> 35 years), hypertensive women who also smoke Hypertension was found to be a risk factor for both users and nonusers, for both hypes of strokes will be smoking interacted to increase the risk for hemorrhagic strokes in a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to a for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used and contraceptives, 2.6 for smokers who did not use oral contraceptives, 1.6 for smokers who add not use oral contraceptives, 1.6 for smokers who used oral confraceptives, 2.6 for smokers who severe hypertension. The attributable risk is also greater in older women.

I observe related risk of vascular disease form and contraceptives. A positive association has been observed between the amount of estrogen and progestogen in and contraceptives and the risk of vascular disease. A decline in serum high-density ipoproteins has been associated with an increased incidence of ischemic heart disease Because estrogens and progestogen of the nature and obsolute amount of progestogen and employed progestogen and progestogen and the nature and obsolute amount of progestogen and several progestory of the amount of progestogen and the nature and obsolute amount of progestogen services and progestogen and progestogen in the contraceptive depends on a both of the analysis of the considered in the choice of an oral contraceptive depends and progestogen and progestogen is in keeping with good

e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for e reassence or insk of vascular disease intere are two studies which have shown persistence of risk of vascular disease for ever users of oral contraceptives in a study in the United States, the risk of developing myocardial infarction discontinuing oral contraceptives persists for all east 9 years for women 40-49 years who had used and contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for all least 6 years after discontinuation of aral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estracens.

ot estrogens. Outstanders were perionted with concurrence formations committed to the controlled of the consocial with different methods of controception at different ages. These estimates include the combined risk of death associated with different methods of controception at different ages. These estimates include the combined risk of death associated with controceptive methods plus the risk attributable to pregnancy in the exent or method foliure Each method of controception has its specific benefits and risks. The study concluded that with the exception of in-controceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of brith control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age to crai-controceptive users is based on dara gathered in the 1970's – but not reported until 1983. However, current clinical practice involves the use of lower estrogen does formulations combined with careful restriction of oral-contraceptive use to women who do not have the various ists factors isted in this labeling. Because of these changes in practice and, also, because of some imitted new data which suggest that the risk of contiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Moternal Health Drugs Advisory Committee vas asked to review tops. In the processing of the controlled with oral-contraceptive use for age effect and of an health pronouncy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have excess to effective and acceptable means of contraception. Therefore, the controlled between a controlled to the lowest possible dose formulation that is effective.

is effective

3. Carcinoma of the Reproductive Organs. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarion and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast concer, regardless of the age and partly of list use or with most of the marketled brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for of least a decade following large-term use. A few situaties have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonursers and differences in age at start of use, has been destained. Some studies suggest that and oral-contraceptive use has been associated with an increase in the risk of cervical intrapsified neoplassia in some populations of women. However, there continues to be controversy about the extent to which such indings may be due to differences in sexual behavior and other factors in spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. Heactic Neopolassia Benian headtic adenomous oral essociated with an increase in the sufficiency to the incidence of benian.

4 Hepatic Neoplasia Bengin hepatic adenorms are associated with oral-contraceptive use, eithough the incidence of bengin tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/ 100.000 for users, a risk that increases after four or more years of use Rupture of rare, bengin, hepatic adornous may cause death through intro-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatic-cellular.

carcinoma in long-term (> 8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users. 5 *Coular Lesions*. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision, onset of prophosis or dipipion, oppliedema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

token immediately.
6. Oral-Controceptive Use Before or During Early Pregnancy Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral confraceptives prior to pregnancy Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral confraceptives to induce withdrawal bleeding should not be used as lest for pregnancy. Oral confraceptives should not be used so lest for pregnancy. Oral confraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed have consecutive periods, pregnancy should be ruled out before continuing oral-confraceptive use if the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-confraceptive use should be discontinued if pregnancy is confirmed.

7. Galibiadder Disease Earlier studies have reported an increased lifetime relative risk of authoridate supregrup users of oral.

To allibidate Disease Earlier studies have reported an increased lifetime relative risk of galibidater surgery in users of oral controceptives and estragens. More recent studies, however, have shown that the relative risk of developing galibidater disease among prol-contraceptive users may be minimal. The recent findings of manimal isk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estragens and progestagens.

tormulations containing lower hormanal doses of estrogens and progestagens.

8. Carbohydrate and Lipid Medabolic Effects. Oral contraceptives have been shown to cause grucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hypernsulinism, white lower doses of estrogen cause less glucose intolerance Progestagens increase insulin secretion and create insulin resistance, his effect varing with different progestational agents. However, in the nondiabetic women, rario contraceptives appear to have no effect on tasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking and contraceptives. A small proportion of women with have persistent hyperfrighycendemia while on the pill. As discussed earlier (see "Womings" to and bt.), changes in serum frighycendes and lipoprotein levels have been reported in oral-contraceptive users.

9. Elevated Blood Pressure. An increase in blood pressure has been reported in women taking and contraceptives and this increase is more likely in older and-contraceptive users and with continued use. Data from the Roya: College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestagens. Women with a history of hypertension or hypertension either diseases, or real diseases should be encouraged to use another method of contraception. If women with hypertension elect to use and contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, and contraceptives, and there is no difference in the occurrence of hypertension on manna elevation of blood pressure occurs, and contraceptives, and there is no difference in the occurrence of hypertension on generand near-users.

or imperioration unity generation for use the control of the control of the data the with a new pattern that is recurrent, persistent or severe requires discontinuation of oral controceptives and evaluation of the cause.

Tell of severe requires aiscommunion or ora-commonships and evaluation or included in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestagen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of break-through bleeding, as in the case of any abnormal vaginal bleeding; if pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or alignmenorrhea, especially when such a condition was preexistent.

tormulation may solve the procern. In the event of amenormed, pregnancy snows are ruled out some women may encounter post-full amenormed or oligomenormed, especially when such a condition was preexistent.

Procurtions

1. PHYSIGAL EXAMINATION AND FOLLOW UP A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests in case of undiagnosed, persistent or recurrent abnormal vaginal bleeding opportune diagnoses and interest of the process of the control of hyperpropriate diagnoses and interest of the process of

Information for the Patient See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reachons has been associated with the use of oral contraceptives (see "Warnings" section) inhornbopinethetis, arterial thromboers been pulmonary embolism, impropriate inhornbost, by the propriet is a pulmonary embolism, impropriate inhornbost, hyperfension, galibilitader disease, heptic adenomos or bening liver trumors.

There is evidence at an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed inesenteric thrombosis; retinal thrombosis.

The following adverse reactions have been reported in options receiving and contraceptives and are believed to be drug related nausea, worlding, gastrointestinal symptoms (such as abdominal cramps and blooting), breakthrough bleeding, spotting, change in menstrual flow, amenorthea, temporary infertility after discontinuation of treatment, edema, melasma which may persist, breast changes tenderness, enlargement, secretion, change in weight (increase or decrease), change in cervical erosion and secretion, diminution in lactation when given immediately postportum, cholestatic journaice, migratine, rosh (altergic), mental depression; reduced tolerance to carbothydrates, vaginal candidiasis; change in corneal curvature (steepening), intolerance to control tenses. to contact lenses

to confact lenses.

The following adverse reachins have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted, congenital anomalies, premenstrual syndrome, cataracts, apitic neuritis, changes in appetite, cystitis-like syndrome, headache, nenousness, dizziness, hissultism, loss of scalip hair, erythema multiforme, cerebral vascular disease with mitral valve prolopse, fupus-like syndromes, erythema noolosum, hemorrangic eruption, organitis, porphyring, impaired renal function, hemolytic uremic syndrome, Budd Chiari syndrome, acne, changes in libido, calitis, sickle-cell disease

Overdosage
Sentous ill effects have not been reported following ocule ingestion of large doses of oral contraceptives by young children
Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits
The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of meeting 0.035 mg of ethinyl estradiol or 0.05 studies which largely talkzed ordi-confraceptive formulations containing doses exceeding 0 035 mg of ethinyl estradiol or 0 05 mg of mestranol.
Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorthea.
Effects related to inhibition of avulation, decreased incidence of functional avarian cysts, decreased incidence of ectopic pregnancies.

narrows Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of avanan cancer Dosage and Administration

CLINICAL SECTION

Clinical Opinion

An epidemic of antiabortion violence in the United States

David A. Grimes, MD,^a Jacqueline D. Forrest, PhD,^b Alice L. Kirkman, JD,^c and Barbara Radford, MA^c

Los Angeles, California, New York, New York, and Washington, D.C.

From 1977 to 1988, an epidemic of antiabortion violence took place in the United States, involving 110 cases of arson, firebombing, or bombing. The epidemic peaked in 1984, when there were 29 attacks. Nearly all sites (98%) were clinics that provided abortions. Facilities in 28 states and the District of Columbia were involved. The national rate of violence was 3.7 per 100 abortion providers and 7.2 per 100 nonhospital abortion providers. The national ratio of violence per 100,000 abortions performed was 0.6. Arson was both the most frequent (39% of all cases) and the most damaging (mean cost \$141,000) type of violence. The epidemic appears partially attributable to multiple point-source outbreaks of violence caused by small numbers of individuals or groups. Thirty-three persons have been convicted to date. Vigorous prosecution of perpetrators and the reemergence of clinics after damage probably helped to curb the epidemic. (AM J OBSTET GYNECOL 1991;165:1263-8.)

Key words: Abortion; abortion, induced; abortion, therapeutic; abortion providers; violence

Harassment and intimidation of providers of abortion services have become widespread in the United States. For example, 47% of abortion providers experienced at least one type of antiabortion harassment in 1985. These activities have ranged from jamming of telephone lines to picketing the homes of physicians to vandalism.2 In recent years, however, the controversy over abortion has taken a destructive turn, resulting in an epidemic of antiabortion violence across the United States. Since 1977 > 100 attempted or completed arsons and bombings have caused millions of dollars of damage and disrupted the provision of health care to large numbers of women. Because this epidemic of violence directed against health care providers is unique in American medicine and because its medical and social implications are profound, we conducted this study to characterize the epidemic.

From the Department of Obstetrics and Gynecology, University of Southern California School of Medicine, The Alan Guttmacher Institute, New York, and the National Abortion Federation, Washington, D.C.

Material and methods

We defined a case of antiabortion violence as an attempted or completed act of arson, bombing, or firebombing directed against an abortion provider or an organization supportive of abortion rights. Cases were identified through the ongoing surveillance of the National Abortion Federation, with the assistance of the United States Bureau of Alcohol, Tobacco and Firearms. Through interviews with the victims and collaboration with law enforcement officials, we determined the date of the occurrence, the city and state, the name and type of facility or organization, the type of violence committed, the estimated damages, and whether a perpetrator was convicted. This report covers episodes of antiabortion violence from Jan. 1, 1977, to Dec. 31, 1988.

We characterized the epidemic by time, victim, and place. We also examined the acts of violence by type and destructiveness. To portray the "vectors" of this epidemic, we also reviewed the convictions of the perpetrators. We calculated the frequency of antiabortion violence by state using three different denominators: the number of abortion providers, the cumulative number of abortions performed in each state from 1977 to 1988, and the estimated number of women aged 15 to

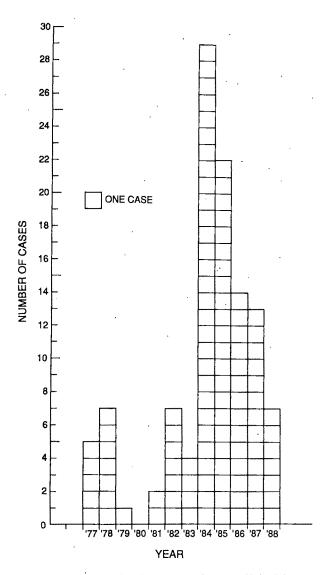

Fig. 1. Cases of antiabortion violence by year, United States, 1977 to 1988.

44 years in each state as of July 1, 1982. Numbers of providers and abortions by state were obtained from surveys by the Alan Guttmacher Institute, ³⁻⁷ with the exceptions of the years 1983 and 1986. Since the institute did not conduct a survey for those years, we used the average number of abortions for 1982 plus 1984 for 1983 and 1985 plus 1987 for 1986. Estimates of the numbers of women of reproductive age (15 to 44) by state for 1982 were obtained from the United States Bureau of the Census. This year was in the middle of the study interval and was selected as a standard for comparison.

To examine the risk of antiabortion violence by type of provider, we calculated violence rates per 100 providers and violence ratios per 100,000 abortions performed. We also sought to identify clusters of cases, which would suggest a common source. For the pur-

poses of our analysis we defined a cluster of cases as two or more cases occurring in the same calendar month in the same state or in a contiguous state. We also examined the correlation between attack rates and percentage change in the number of abortions by state.

Results

From 1977 to 1988, 110 cases of antiabortion violence were identified. The epidemic peaked in 1984, with partial resolution of the epidemic in subsequent years (Fig. 1). Twenty-nine cases occurred in 1984, which was four times the number in any preceding year. One percent of all abortion providers in the United States were targets of attempted or completed arson or bombing in 1984. The ratio of violence in that year was 1.8 episodes per 100,000 abortions.

The targets of antiabortion violence were almost exclusively health care providers. One hundred eight cases (98%) involved providers, whereas the other two victims were organizations related to abortion rights. In July 1984 the office of the National Abortion Federation in Washington, D.C., was damaged extensively by a propane bomb. In November 1984 the Washington, D.C., office of the American Civil Liberties Union was bombed while an employee was present. This attack was classified as abortion related, since the group that bombed the ACLU was convicted of attacking the National Abortion Federation and a number of clinics.

Nonhospital providers (clinics and physicians' offices) were the only providers attacked (Table I). A total of 80 different facilities were attacked, 20% more than once. Nine were attacked twice, three facilities three times, three facilities four times, and one facility five times during the study interval. The number of attacks among these 80 providers was 1.4 ± 0.8 (mean \pm SD).

Antiabortion violence was committed from coast to coast (Fig. 2). Twenty-eight states and the District of Columbia experienced one or more episodes. The largest number of cases occurred in Ohio (n=16), followed by California (n=10), Texas (n=9), and Florida (n=8). However, the highest rate of violence per 100 nonhospital providers occurred in Minnesota, followed in decreasing order by Delaware, Ohio, and North Dakota. Violence ratios (number of cases per 100,000 abortions performed) were highest for Vermont, followed by Oregon, Minnesota, and North Dakota (Table II). The national ratio from 1977 to 1988 was 0.6 cases per 100,000 abortions.

Violence levels by size of state revealed a different pattern. The highest ratios of violence in the 1977 to 1988 period per million women of reproductive age in 1982 were seen in the District of Columbia (17.8), followed by Vermont (15.7), Oregon (11.0), and Minnesota (7.1). The national ratio was 2.0 cases per million women of reproductive age.

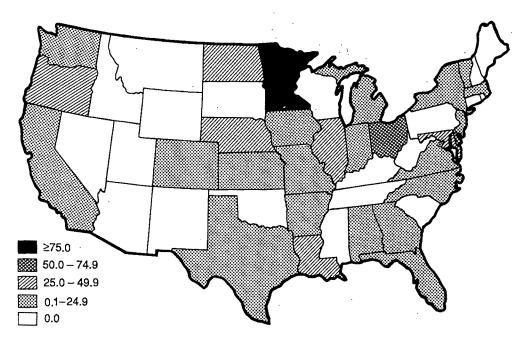

Fig. 2. Rates (number of cases per 100 nonhospital providers) of antiabortion violence against nonhospital providers, by state, United States, 1977 to 1988.

Table I. Rates of antiabortion violence against providers, by type, United States, 1977 to 1988

Type of provider	No. of attacks*	No. of providers†	Rate‡
Hospital Nonhospital	0 108	1405 1503	0.0 7.2
TOTAL	108	2908	3.7

^{*}Excludes two attacks against nonproviders.

Between 1977 and 1988 the number of abortions in the United States increased at an average annual rate of 1.9%. In those areas that had experienced violent attacks against abortion providers, the average annual increase was 2.0%, compared with 1.4% in other states. The correlation between the proportion of abortion providers subject to violent attacks over the 1977 to 1988 time period and the percentage change in the number of abortions between 1977 and 1988 was not significant.

The clustering of episodes both temporally and geographically suggests that the epidemic can be partially explained as multiple point-source outbreaks. Eighteen clusters of cases accounted for 41% of all episodes of antiabortion violence. Forty-five cases were clustered in groups of two to four episodes in the same month in the same locale. Convictions of perpetrators support the multiple point-source outbreak explanation. Several individuals and groups were convicted of multiple

acts of violence. Fifteen individuals or groups (total of 33 persons) have been involved with 42 separate cases (38%). The mean number of cases accounted for by these 15 "vectors" was 2.8, with a range of 1 to 10.

Those convicted were implicated in 8 of the 18 clusters identified epidemiologically, leaving 10 clusters without convictions. One suspect has been indicted on charges related to two arsons but has remained a fugitive because of failure to appear at sentencing on unrelated charges. Two other perpetrators confessed but were not convicted; one was declared incompetent to stand trial and was committed to a state mental institution, and the other was found not guilty by reason of insanity.

The nationwide conviction rate was 39%, although rates varied widely from state to state. All cases resulted in conviction of the perpetrators in the District of Columbia, Maryland, Virginia, Delaware, Indiana, Louisiana, and North Dakota. Some states with large num-

[†]As of 1982.

^{*}Excludes two attacks against nonproviders in the District of Columbia.

bers of cases (Ohio, Oregon, and Texas) failed to convict any perpetrators.

Arson was the most frequent type of violent act. Arson and attempted arson were involved in 39% and 13% of cases, respectively. Bombing (21%) and attempted bombing (15%) were next in frequency. These included one chemical bomb, one propane bomb, one pipe bomb, and one package bomb designed to explode on opening. The package bomb was intercepted at the clinic, and postal officials were notified. Similar packages were found at the local post office addressed to three different clinics. Firebombing (10%) and attempted firebombing (3%) were the least frequent types of violent acts.

Violence involving fire caused more extensive damage than did violence involving explosion. The estimated damages from arson were known for 37 of the 43 cases; the total losses were \$5,215,500 with a mean \pm SD of \$141,000 \pm \$273,700 per case. Damage estimates were available for 7 of the 11 firebombings; the total losses were \$890,000, with a mean \pm SD of \$127,100 \pm \$108,600 per case. Similar data were available for 22 of the 23 bombings; the total losses were

\$1,501,000, with a mean \pm SD of $$68,200 \pm $70,000$ per case. The twofold difference in damages between incendiary and explosive devices is likely an underestimate; several arsons totally destroyed the building, and no replacement value was available. The single most expensive act of violence occurred in Texas in February 1985, when a gasoline-ignited fire destroyed an entire shopping center valued at \$1,500,000 and injured two firefighters.

Comment

One definition of an epidemic is an "unusually frequent occurrence of disease in the light of past experience." By this definition any act of arson or bombing directed against a health care provider or related organization constitutes an epidemic. The epidemic of antiabortion violence in the United States from 1977 to 1988 was a social phenomenon without precedent. To our knowledge this epidemic was the first time in our nation's history that health care providers have been singled out as targets of violence in pursuit of a social agenda. Other controversial areas of medicine, such as life-support systems, organ transplantation,

[†]Per 100,000 abortions performed.

blood banking, and in vitro fertilization, also may be in jeopardy.

Harassment and violence have become part of a strategy of some antiabortion elements; the dramatic increase in violence seen in 1984 has been attributed to their growing frustration by their failure to overturn Roe v Wade and prohibit abortions.2

This frustration was intensified in the summer of 1983 by three factors. The first was a forceful reaffirmation by the United States Supreme Court of a woman's right to abortion and a rejection of restrictions that would limit access to abortion (City of Akron v Akron Center for Reproductive Health, 103 S Ct 2481). The second was the United States Senate's rejection of a constitutional amendment that would allow states to prohibit abortion. The third was the Senate's earlier tabling of the human life statute, which would allow Congress to bypass the constitutional amendment process and to prohibit abortion by another mechanism. These setbacks were difficult for some abortion opponents to accept, given the expectations occasioned by the election of Ronald Reagan to the presidency. Some of the more radical elements gave up hope for judicial or legislative change and instead embarked on a militant course of action.2

Several factors probably helped to curb the epidemic. One was vigorous investigations by local and federal law enforcement agencies, notably, the Bureau of Alcohol, Tobacco and Firearms. The bureau has primary responsibility for federal gun control, explosives control, and antiarson laws. Arrests and convictions may have deterred others. The most severe sentence has been 30 years and the most severe fine \$353,000. Thirty-year sentences were given to two men purporting to be members of a radical antiabortion group known as the "Army of God"; they were convicted of attacks against three abortion clinics and the kidnapping and extortion of a physician. In addition, most facilities that were attacked did not close permanently, so that the disruptions were temporary.

Clinics were the principal targets of antiabortion violence. This finding is consistent with the observation that clinics also are the chief targets of harassment.1 A survey of providers revealed that several factors were significantly related to harassment: type of facility (e.g., clinic vs physician's office), region of the country (higher in the Midwest and South), and proportion of patient visits that involved abortion services. Factors not associated with the likelihood of harassment included number of abortions performed beyond 400 per year, recent change in number of abortions performed, maximum gestational age at which abortions are performed, and cost of the procedure.1 Clinics provide the majority of abortions in the United States and are both visible and vulnerable. Unlike hospitals, which are open for business around the clock, clinics have long periods of time when they are vacant and accessible to attack.

Some states had a disporportionate amount of antiabortion violence. These included both populous states such as Ohio and less populous states such as North Dakota, Delaware, Minnesota, North Dakota, Ohio, and Oregon consistently ranked high in frequency of violence when analyzed according to the number of nonhospital providers, number of abortions performed, and population of women of reproductive age. The District of Columbia had a disproportionately high violence ratio per million women of reproductive age because it has a relatively small population but serves as a referral center for abortion services.

The true cost of this epidemic is hard to estimate. As noted, the direct cost of \$7.6 million is a substantial underestimate because of the exclusion of a number of facilities that were completely destroyed. The related costs of increased expenses for legal and security services, increased fire and casualty insurance, new licensing requirements, and staff recruitment have not been estimated but are large. In addition, the indirect costs of time lost from work during repair and reconstruction are substantial. Patients seeking abortion or other services were forced to postpone care or transfer to another provider. The cost of investigation, prosecution, and incarceration of perpetrators also is large. These costs may translate into higher fees for patients and rising costs of law enforcement.

Even though the costs of this epidemic have been great and some facilities have had to interrupt or discontinue providing abortion services, the violent attacks have not led to fewer women having abortions. There is no statistically significant relationship between the change in the number of abortions between 1977 and 1988 and the levels of violence among nonhospital pro-

This epidemic of antiabortion violence represents a minority of the hostile acts against abortion providers during the study interval. Between 1977 and 1988, the following incidents were reported to the National Abortion Federation: clinic invasion, 222; clinic vandalism, 220; bomb threats, 216; death threats, 65; assault and battery, 46; burglary, 20; and kidnapping, 2. The actual number of hostile acts may be substantially higher, because these figures reflect only voluntary reports.

The majority of United States citizens oppose violence against abortion facilities.1 Clearly, the public suffers from this violence, which is sometimes indiscriminate. For example, a Planned Parenthood Clinic in Georgia was attacked by a firebomb in September 1984; the clinic does not provide abortions but, rather, counseling and contraception that help to avoid the need for abortion.

Abortion will likely remain one of the most contro-

versial social issues of our time. Arson, bombing, and millions of dollars of damage to health care facilities have neither contributed to the debate over abortion nor decreased the numbers of abortions performed. Sex education, personal responsibility, and better contraceptive practices will help to reduce the need for abortions; Molotov cocktails will not. When this is understood, the epidemic of antiabortion violence may finally end.

Multifetal pregnancy reduction and disposal of untransplanted embryos in contemporary Jewish law and ethics

Richard V. Grazi, MD, and Joel B. Wolowelsky, PhDb Brooklyn, New York

Recent responsa (rabbinical rulings) on multifetal pregnancy reduction and disposal of untransplanted embryos indicate that the position of contemporary Jewish law and ethics on these specific issues differs strongly from the *Instruction* of the Roman Catholic Church and is closer to the view adopted by the Ethics Committee of the American Fertility Society. (AM J OBSTET GYNECOL 1991;165:1268-71.)

Key words: Multifetal pregnancy reduction, embryos, ethics

In 1988, the Ethics Committee of the American Fertility Society published its reaction to the Roman Catholic *Instruction*, which condemned, *inter alia*, both the destruction of fertilized eggs from the moment the zygote has formed and the reduction of multifetal pregnancies. The Ethics Committee published a more comprehensive statement in 1990.) We present here a report on a number of recent responsa (rabbinic rulings) on these two issues, which have initiated the discussion for contemporary Jewish scholars addressing the matter.

The Jewish "magisterium" consists of the Bible, the Mishnah and Talmud, and universally accepted codifications such as Maimonides' Mishneh Torah or the later Shulhan Arukh. These are the sources for the investigation of the traditional Jewish position on any ethical or legal issue. Rulings on contemporary issues cannot be promulgated by any central authority, there being no formal hierarchical structure to the various contemporary rabbinic authorities and courts. Positions on contemporary issues are developed by circulation of responsa to questions posed to various rabbinic authorities. Collegial review and community acceptance eventually allow for specific opinions to emerge as dominant. (However, even when one view surfaces as authoritative, individual rabbis or laymen will often defer to their local authority whose position is considered decisive.) Not all authorities of Halakhah (traditional Jewish law) allow in vitro fertilization, even if the husband is the sperm donor.4-6 The responsa quoted here assume the questioner has accepted the lenient opinions permitting in vitro fertilization.

Status of embryo

One need not look past the famous Mishnah allowing for abortion of a fetus to realize that traditional Jewish ethics and law differentiates between an unborn fetus and a born human being. The Mishnah rules that "[if] a woman is in hard labor, they chop up the child in her womb and they remove it limb by limb, because her life takes precedence over its life. [If] its greater part had gone forth, they do not touch it, for they do not set aside one life on account of another life."7

Maimonides8 codifies this as law, declaring the fetus in such a case to be a rodef, an agressor pursuing another to kill him or her and who, according to Jewish law, must be killed rather than allowed to accomplish the murder. But if the baby's head has emerged, it attains human status and may not be touched, he continues, "for one may not put aside one life for the sake of another. This is the way of the world." This distinction between an unborn fetus and a born human being is rejected by the Roman Catholic Instruction, which reasserts the position that "from the time the ovum is fertilized, a new life is begun which is neither that of the father nor of the mother; it is rather the life of a new human being Right from fertilization is begun the adventure of a human Life 2

Within Jewish law, there are many situations in which a pregnancy may be terminated, although abortion on demand is repulsive to the ethics of the Halakhah. (Bleich⁹ has summarized the extensive halakic literature on the subject.) Still, nontransplanted embryos fertilized artificially in vitro have no standing as fetuses in Jewish law. In a recently published responsum, Haim David Halevi,10 Chief Rabbi of Tel Aviv, rules that "all eggs fertilized in vitro have no standing as embryos...and one may discard them if they were not chosen for implanting, as the law of abortion applies only to [procedures in] the womb But in vitro, as was said, there is no prohibition at all."

A similar ruling is offered by Mordechai Eliyahu,11 Chief Rabbi of Israel, who writes that "all fertilized eggs which are destined to be implanted in the mother's womb should not be destroyed, as a live fetus will yet develop from them. But those eggs which have not been chosen for implantation may be discarded." Neither authority offers any detailed analysis of his legal ruling, apparently considering the position to be obvious and noncontroversial from the perspective of Jewish law and ethics. Indeed, as Bleich¹² points out in his recent summary of halakhic attitudes toward fetal research, an aborted fetus in the early stages of gestation does not require burial.

It is not unreasonable to assume that to some extent these rulings are based on the Talmudic statement that an embryo is "mere water" within the first 40 days of conception and that it is not viable in vitro.13 If the embryo could be maintained artificially outside of the womb until much later stages of gestation, it is not clear if these rulings would apply.

Related ethical issues

These rulings have interesting implications for a number of other issues. Bleich12 has noted that the tissue of a spontaneously aborted fetus may be used for research purposes if there is a reasonable basis for assuming that practical medical benefits will ensue within a reasonable time period (the specific details of which require individual analysis). One might well argue that untransplanted embryos, which never had viable status, might be used for the purpose of research before they are discarded.

One must keep in mind, though, that those rabbinic authorities who allow in vitro fertilization do not consider the procurement of the sperm to be a "wasting of seed" because the procedure is used to overcome existing problems of infertility. It is not at all clear that rabbinic approval would be forthcoming for in vitro fertilization solely for the purpose of research. Likewise, it is not certain that properly obtained semen may be used to fertilize more eggs than would be necessary to assure a sufficient number of embryos for transplantation to obtain "excess" untransplanted embryos that would be used for research purposes. Nevertheless, "Jewish law does not posit . . . an exclusionary rule that would, post factum, preclude the use of illicitly obtained tissue for an otherwise sanctioned purpose" such as medical research.12

We may also surmise that the embryos may be examined for the purpose of sex selection. The technology to do this is already available.14 The primary halakhic concern is not with the decision to engage in sex preselection but with the method to be used in effecting sex determination.15 For example, aborting a fetus that is not of the desired sex is unequivocally prohibited, but if in vitro fertilization is used to overcome existing problems of infertility and only some of the embryos will be transplanted, it would seem that selecting an embryo of the desired sex would be allowed.

Similarly, screening embryos for genetic defects would be permitted. However, permitting in vitro fertilization solely for the purpose of genetic screening rather than for overcoming a fertility problem awaits a further, more complete analysis.

Multifetal pregnancy reduction

The issue of fetal reduction is more problematic. Increased use of ovulatory drugs and related therapies has yielded an increasing number of multifetal pregnancies. As a result of the premature births associated with such pregnancies, these fetuses are in significant jeopardy. Artificial reduction of the number of fetuses has been suggested as a method of reducing this risk, yet each individual fetus has standing in Jewish law, albeit not as a full person. There being no blanket permission for abortion, a more detailed justification of any ruling allowing multifetal pregnancy reduction is required.

As the Committee on Ethics of the American College of Obstetricians and Gynecologists¹⁶ takes note, a distinction may be made between multifetal pregnancy reduction and selective termination of an anomalous fetus. "Insofar as the intention of selective termination is different from that of other multiple fetal reductions, its ethical rationale is importantly distinctive. That is, the intention in selective termination is to avoid having a child with a known medical problem, whereas the intention in multifetal reduction is to prevent problems that are secondary to multifetal gestation and premature birth."

The question of multifetal pregnancy reduction was recently taken up by Yitzhak Zilberstein¹⁷ in a responsum to the Israeli Medical-Halakah Group. If the mother's life is in danger, he writes, each fetus is a *rodef* and can be killed to save the mother, as noted above. But if the danger is to the various fetuses and not to the mother, each fetus is an aggressor and victim with equal status; it therefore might not be permissible to put aside one soul for the sake of another.

Searching for a legal analogy for this situation, Zilberstein focuses on the case of a group of people who are in mortal danger and who can be saved by sacrificing one innocent member of the company. He notes that most halakhic authorities agree that in such cases all must allow themselves to die rather than themselves give up an innocent person. However, he finds a number of authorities who limit these rulings to cases in which in theory the innocent person who would be sacrificed might have been able to escape. If it were absolutely certain that all would be lost unless one were forfeited, these authorities would allow some innocent people to be selected by lottery and sacrified to save the others.

These conclusions apply to cases concerning full humans who have standing as viable persons. However, Zilberstein continues, our case concerns fetuses, all of which are already condemned to death. Multifetal pregnancy reduction should therefore be allowed, he ruled, noting that this might then be a case of "fetal life-saving" rather than "fetal reduction." (As Berkowitz and Lynch¹⁸ have noted, the term chosen to describe a procedure such as this is significant.) Shlomo Zalman Auerbach, one of the leading contemporary rabbinic

authorities in Jerusalem, is quoted elsewhere as also tending to allow the procedure to save the remaining fetuses.¹⁹

Zilberstein's decision seems to assume that without multifetal pregnancy reduction none of the fetuses would survive the multiple pregnancy. This suggests that if the medical indication is that they would survive, albeit with serious physical and/or mental deficiencies, multifetal pregnancy reduction might be ethically prohibited. However, Halevi¹⁰ also allows the procedure without presuming that all were otherwise doomed to death. He notes that there is no unanimity of opinion among halakhic authorities concerning abortion, with some taking a most restrictive position and others allowing abortion of Tay-Sachs fetuses even in the third trimester. As the vast majority hold that the abortion of nonviable fetuses is not homicide at all, he feels that a lenient position should be maintained because without reduction the fetuses most probably would be born prematurely and with serious physical and/or mental disabilities. He10 therefore allows reducing the pregnancy to the extent necessary to ensure that the remaining fetuses would be born healthy and whole.

Eliyahu¹¹ also allows the procedure, adding that the reduction could be done at any stage of the pregnancy, although it is better to do it as early as possible, preferably within the first 40 days, the period for which halakhists take the most liberal position on abortion. It would therefore be preferable, from this perspective, to use transvaginal sac aspiration rather than intracardiac potassium chloride administration via the transabdominal route, because the former may be done at an earlier stage of pregnancy.²⁰

Zilberstein, Halevi, and Eliyahu all maintain that the number of fetuses to be destroyed is a medical question and should be decided by the doctors involved, who must determine the minimum number that need to be killed to ensure a good prognosis for the mother and remaining fetuses. (Auerbach is not quoted on the issue.) This puts an ethical burden on the medical professional to be completely current on the statistical and medical studies associated with multifetal pregnancy outcome and multifetal pregnancy reduction, so that the absolute minimal number of fetuses to be killed could be determined reasonably. No halakhic authority suggests multifetal pregnancy reduction for convenience or choice, such as reducing twins to singletons.

Comment

Jewish law and ethics disagrees with the *Instruction*'s position that "no moral distinction is considered between zygotes, pre-embryos, embryos or fetuses." It maintains that eggs that have been fertilized in vitro and that have not yet been transplanted have no stand-

ing and may be discarded. Multifetal pregnancy reduction is a morally acceptable procedure, although care must be taken to kill the minimum number of fetuses that will reasonably assure that the remaining fetuses will be born healthy and whole.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of \$61.00 for domestic, \$88.27 for Canada, and \$84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. Payment must accompany all orders. Contact Mosby-Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Clinical Articles

Should anticardiolipin tests be performed in otherwise healthy pregnant women?

E. Nigel Harris, MPhil, MD, DM, and Joseph A. Spinnato, MDb Louisville, Kentucky

Positive anticardiolipin and lupus anticoagulant tests are not confined to patients with the antiphospholipid syndrome, and the usefulness of these tests in healthy pregnant women is uncertain. This study sought to determine the prevalence of anticardiolipin antibodies and correlation with pregnancy outcome in 1449 pregnant women. Results were compared with 40 patients with the antiphospholipid syndrome. Persistence of positive anticardiolipin antibody tests was also ascertained. Twenty-six of 1449 sera (1.79%) were immunoglobulin G anticardiolipin positive, and 63 (4.3%) were immunoglobulin M anticardiolipin positive. Twenty-three of 26 positive for immunoglobulin G anticardiolipin and 55 of 63 positive for immunoglobulin M anticardiolipin results were low. Anticardiolipin positivity did not correlate with complications or outcome. Immunoglobulin G isotype and level distinguished patients with antiphospholipid syndrome from otherwise healthy women with positive anticardiolipin tests. In healthy pregnant women positive anticardiolipin tests occur infrequently, at low levels, and are rarely associated with adverse pregnancy outcome. This test should be requested only when the antiphospholipid syndrome is suspected. (AM J OBSTET GYNECOL 1991;165:1272-7.)

Key words: Anticardiolipin, lupus anticoagulant, antiphospholipid syndrome, pregnancy loss, systemic lupus erythematosus

Antibodies that bind phospholipids are detected by one of three tests: lupus anticoagulant, anticardiolipin, or Venereal Disease Research Laboratory tests.1 These antibodies have been associated in some, but not all, studies with recurrent pregnancy loss, arterial or venous thrombosis, and thrombocytopenia. Of the three tests, the anticardiolipin test is accepted generally as the most sensitive, the easiest to obtain, and the subject of most recent efforts to standardize; hence, it has been widely adopted by university and commercial laboratories. In spite of this, the association of anticardiolipin antibodies with fetal loss has been the subject of much controversy.²⁻⁶ Physicians are often uncertain whether this test should be ordered in otherwise healthy pregnant women and what action should be taken if a pregnant woman is found to have a positive test. The latter question is of vital importance, because affected women with recurrent pregnancy losses have been reported to have successful pregnancy outcome after treatment with prednisone, heparin, or high-dose immunoglobulin. These treatment modalities may be efficacious but have a high risk of side effects or, in the case of immunoglobulin therapy, may be expensive. Hence, the decision to treat should be based on clear guidelines.

Recently some investigators have examined anticardiolipin tests prospectively in otherwise healthy populations of pregnant women.^{8,9} One study reported an association of positive test results with low-birth-weight babies and spontaneous abortion,⁸ and another found an association with spontaneous abortion in those few women who had moderate or high immunoglobulin G (IgG) anticardiolipin levels.⁹

This report is a survey of sera for anticardiolipin antibodies in 1449 women admitted to the obstetric wards of a local hospital, to determine the degree to which positive anticardiolipin tests are associated with pregnancy outcome and complications. We compared the results of our study population with a group of 40 patients with the antiphospholipid syndrome.

Methods

All women admitted to the obstetric wards of the Alliant Health Care System (Louisville, Ky.) between

May 15, 1989, and March 15, 1990, were told of the study, and permission was sought to have their blood tested for anticardiolipin antibodies at the time blood was being drawn for other routine tests. A total of 1449 women consented to participate in the study. Most of the patients were at or near term ($\pm 90\%$). While patients with late second-trimester and early third-trimester complications were actively enrolled in the study, such patients were few. After consent was obtained, the admitting nurse filled in a form with the patient's name, age, race, and specified pregnancy complications. Pregnancy complications specified were preeclampsia, eclampsia, chronic hypertension, insulin-dependent diabetes mellitus, gestational diabetes, intrauterine growth retardation, abruptio placentae, stillbirth, and preterm labor. There was a category on the form for other complications to be specified. If the pregnancy was not associated with any complications, the nurse entered "none." The frequency of use of aspirin, corticosteroids, or other immunosuppressive therapy was not determined and was assumed to be low.

Sera from 40 patients with the antiphospholipid syndrome were analyzed for anticardiolipin antibodies. These patients were defined as having the antiphospholipid syndrome on the basis of a history of one or more episodes of venous or arterial thrombosis, recurrent abortion or fetal death, or thrombocytopenia associated with a medium- or high-positive anticardiolipin test result or a positive lupus anticoagulant test.1 These test results should have been positive on more than one occasion at least 8 weeks apart.1

The anticardiolipin assay was performed with an enzyme-linked immunosorbent assay method.4 Five milliliters of a clotted blood specimen was obtained from each patient. This specimen was centrifuged for 15 minutes and the sample was stored at -20° C until anticardiolipin measurement was performed. All patients' sera were run at a dilution of 1:50 in duplicate on three different days and the mean level was determined. Samples were analyzed for IgG and IgM anti-

cardiolipin and antibody levels reported in GPL units (for IgG) and MPL units (for IgM).10 Anticardiolipin levels for unknown samples were computed from a log-logistic calibration curve obtained by running five calibration standards on each enzyme-linked immunosorbent assay plate. On the basis of analysis of several thousand normal sera in the past, an abnormal IgG anticardiolipin result was taken as a level >5 GPL units, and an abnormal IgM result was taken as a level >5 MPL units. In addition to reporting antibody levels in GPL or MPL units, a semiquantitative measurement was used11: low, 5 to 20 GPL units (IgG) or 5 to 20 MPL units (IgM); moderate, 20 to 80 GPL units or 20 to 80 MPL units; and high, >80 GPL units or >80 MPL units. The latter semiquantitative designation has enabled better comparison of anticardiolipin results between laboratories.11 The lupus anticoagulant and other antiphospholipids were not assessed in this study.

The frequency of positive anticardiolipin tests between and among subsets of the study group was evaluated with x2 analysis and Fisher's exact test, where appropriate. Significance level was set at $\alpha = 0.05$.

Results

Sera were obtained from 1449 women. Two hundred twenty-eight were nonwhite, and 1221 were white. The mean age of white patients was 27 ± 5 years, and the mean age of nonwhite patients was 23 \pm 5 years. With the exception of stillbirth, there was no statistical difference in the frequency of complications according to race. In spite of its infrequent occurrence, stillbirth (white, 1; black, 3) was statistically more likely among nonwhite patients (p = 0.027). However, anticardiolipin antibodies were not observed among these patients.

Twenty-six (1.79%) of the 1449 serum specimens analyzed were positive for IgG anticardiolipin and 63 (4.3%) were positive for IgM anticardiolipin. These results, defined semiquantitatively-high, medium, low,

^{*}For IgG anticardiolipin, high, >80 GPL units, medium, 20 to 80 GPL units; and low, 5 to 20 GPL units. 12.13 For IgM anticardiolipin, high, >80 MPL units; medium, 20 to 80 MPL units; and low, 5 to 20 MPL units. 12.13

or normal-and classified according to race, are shown in Table I. There was no difference in results according to race. Of the 26 patients with positive IgG anticardiolipin results, 23 were low positive, 3 medium positive and none high positive (Table I). One of the three patients with medium-positive IgG anticardiolipin was already known to us as having the antiphospholipid syndrome (four previous pregnancy losses and multiple deep venous thromboses). The result obtained in this patient was the lowest ever recorded for the 2 years we had been monitoring her. (She was being treated with high-dose prednisone and intermittent immunoglobulin infusions during that pregnancy, which ended in a live but premature birth.) Of the 65 patients with positive IgM anticardiolipin results, 55 were low positive, nine medium positive, and one high positive. The one patient with a high-positive IgM anticardiolipin result also had medium-positive IgG anticardiolipin and was known to have a false-positive Venereal Disease Research Laboratory test result but had no underlying disease. Pregnancy outcome was normal.

1053

None

The overwhelming majority of patients with positive anticardiolipin tests had no complications during pregnancy. Thus 21 of 23 (91.3%) patients with positive IgG anticardiolipin test results and 54 of 63 (76%) patients with positive IgM anticardiolipin results had no pregnancy complications (Table II). Of the three women with medium-positive IgG anticardiolipin results, all had live births, although the one with the antiphospholipid syndrome (as discussed) was treated during pregnancy.

In women with specified pregnancy complications, few had positive anticardiolipin test results, and when these were positive, levels were low. Thus, of the 62 women with preeclampsia, only four had positive anticardiolipin tests, three were low IgM positive and one was low IgG positive. This frequency (4/62) was not

significantly different from that of patients with other complications (7/181) or patients who had no complications (75/1148). The only other complication categories in which test results were positive were abruptio placentae (one low-positive IgM) and seven in the "other" category (Table II).

1148

6.5

Anticardiolipin levels according to isotype in the study population are compared with level and isotype in 40 patients with the antiphospholipid syndrome (Figs. 1 and 2). IgG anticardiolipin levels in most patients with the antiphospholipid syndrome were much higher than any of the IgG anticardiolipin—positive levels in the study population (Fig. 1). Only 20 of the 40 patients with antiphospholipid syndrome had positive IgM anticardiolipin tests and only six of 20 had levels >20 MPL units. In the study population 63 of 1449 patients had positive results, and there were nine patients with levels >20 MPL units (Fig. 2). Thus there was considerable overlap in IgM anticardiolipin levels between the patients with antiphospholipid syndrome and the study patients.

In an effort to determine whether women in the study population might have underlying disorders contributing to positive anticardiolipin tests, e.g., systemic lupus erythematosus or antiphospholipid syndrome, and to determine how long positive test results persisted, we invited all 99 patients with positive test results to return for a more detailed history and repeat anticardiolipin test. Twenty-seven patients returned for a follow-up interview within about 3 months of completion of pregnancy. The patient known to us with the antiphospholipid syndrome is not included in this analysis.

Twenty-three of the 27 patients who returned had had uncomplicated pregnancies. Of the remaining four, one had preeclampsia, one had abruptio placentae, and two had postdate births. On questioning, none

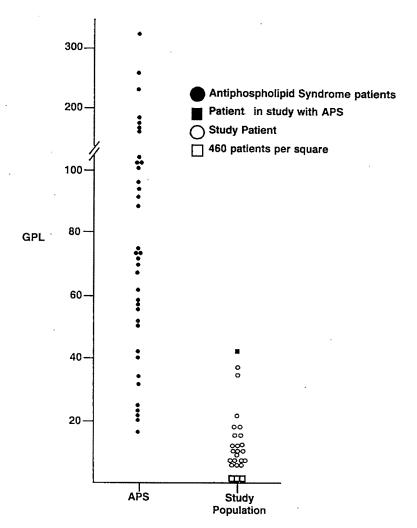

Fig. 1. Comparison of IgG anticardiolipin levels in 40 patients wth antiphospholipid syndrome (APS) with those of 1449 pregnant women in study. Only a minority of pregnant women had positive IgG anticardiolipin results and these were almost always lower than levels in patients with antiphospholipid syndrome. The highest value in study population (43 GPL units) was in a patient with the antiphospholipid syndrome being treated with prednisone and intermittent Ig therapy. This was the lowest result she had ever achieved, and she gave birth to a live baby at 32 weeks' gestation.

of these patients had symptoms of antiphospholipid syndrome, systemic lupus erythematosus, or other autoimmune diseases. Nine of the 26 had a history of abortion, five having one, two having two, one having three, and one having four previous abortions. All patients with histories of abortions had low-positive IgM anticardiolipin results, as did the majority of patients who were screened in this study. Surprisingly, on retesting, 22 of 27 patients remained with positive results at levels comparable with their original values.

Comment

Recent studies have screened healthy pregnant women for anticardiolipin antibodies and sought prospectively to compare positive anticardiolipin test results with outcome. The study by Lockwood et al.8 is

the best known; in their survey of 737 healthy women, they found an association between positive anticardiolipin test results and low-birth weight babies or spontaneous abortion. However, the anticardiolipin test result was infrequently positive in these women, and it appeared that the majority of women tested had low anticardiolipin levels although measurement of levels did not correspond to currently accepted criteria. 10, 11 A second study by Brown et al.9 of 1200 women found only 15 (1.25%) to have positive IgG anticardiolipin tests. Six had moderate- to high-positive IgG anticardiolipin tests, and three of these had spontaneous abortion. They found spontaneous abortion to be no more frequent in women with low-positive test results than in 393 women with negative test results.

We have surveyed sera of 1449 pregnant women at

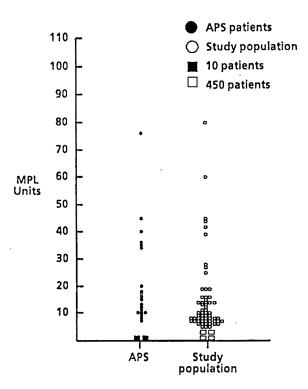

Fig. 2. Comparison of IgM anticardiolipin levels in 40 patients with antiphospholipid syndrome (APS) with those of 1449 pregnant women in study. In contrast to IgG anticardiolipin (Fig. 1), only a minority of antiphospholipid syndrome patients had positive IgM anticardiolipin results, and there was considerable overlap between levels in this group and those of the study population.

or near the time of delivery for IgG and IgM anticardiolipin results and have sought to determine the prevalence of positive test results in these women and the degree to which these tests correlate with pregnancy outcome. The anticardiolipin test used to screen sera utilizes several of the improvements in enzyme-linked immunosorbent assay techniques and units of measurement that have been recommended by two international workshops designed to standardize the anticardiolipin test^{10,11}; hence, we believe our findings can be reproduced in other laboratories.

We found that the prevalence of positive anticardiolipin tests in a population of pregnant women at term is low. Only 1.79% (26/1449) had positive IgG anticardiolipin tests and 4.3% (63 of 1449) had positive IgM anticardiolipin. These prevalences are very similar to those of surveys of large numbers of nonpregnant blood donors (unpublished data) and suggest that normal pregnancies do not induce autoantibody production—a conclusion reached by other investigators. ¹³⁻¹⁵ More importantly, of the 26 patients with positive IgG anticardiolipin results, only four had moderate levels (none were high), and the patient with the highest level was already diagnosed as having the antiphospholipid

syndrome. The infrequency of pregnancies with second-trimester or early third-trimester complications and delivery in this study limits conclusions to be drawn for such patients.

It was noteworthy that when IgG anticardiolipin levels of the pregnant women with positive test results were compared with levels in patients with antiphospholipid syndrome, levels in the latter were higher than those in the former. It was just as important that only a small number of patients with the antiphospholipid syndrome had elevated IgM anticardiolipin levels, and there was considerable overlap of these levels with levels in the pregnant women. Few women with low-positive results had adverse pregnancy outcome; therefore the findings of this study reemphasize findings in some16-19 but not other studies.8, 15 We can only conclude that IgG anticardiolipin results at low levels and IgM anticardiolipin results at low and probably moderate levels are infrequently associated with adverse pregnancy outcome.

The fact that only a minority of women with positive results had adverse pregnancy outcomes identifies a dilemma faced by several other past studies of anticardiolipin antibodies. When populations of pregnant patients or patients with disorders such as systemic lupus erythematosus are screened, the overwhelming majority of positive tests are usually low positive. Recurrent pregnancy losses may be infrequent in these women, although they have positive anticardiolipin test results. Investigators finding these results in patients with systemic lupus erythematosus often conclude that there is no association with recurrent pregnancy losses.20 In fact, the association could well have been missed⁵ because recurrent fetal loss may have occurred only in the infrequent patient with high anticardiolipin levels. (One author, E.N.H., has surveyed sera of patients with systemic lupus erythematosus from a number of institutions in which very few or no serum samples have had anticardiolipin levels in ranges seen in the antiphospholipid syndrome; such series are unlikely to find associations between anticardiolipin antibodies and fetal loss.)

Surprisingly, the positive anticardiolipin results of a majority of patients remained positive for periods at least up to 3 months post partum, although none had clinical features of the antiphospholipid syndrome or systemic lupus erythematosus. One patient (with the highest IgM anticardiolipin level) was known to have a false-positive test result for syphilis, but she had no symptoms of an autoimmune disorder and her two pregnancies were without complications. This finding leads us to conclude that persistently positive tests need not be confined to patients with the antiphospholipid syndrome or systemic lupus erythematosus but may persist for long periods even in the absence of clinically

apparent autoimmune disorders. Perhaps it is in this population of patients with low positive results that abortions occur more frequently, the subpopulations with subclinical autoimmune disease.21-28 The persistence of those antibodies long after pregnancy suggests that the pregnant state did not induce autoantibody production.

On the basis of the above data, we recommend that the anticardiolipin test not be done to screen otherwise healthy women. The test is positive infrequently in this population, and, even when positive, levels are usually low and of uncertain significance. We suggest that aggressive treatment during pregnancy of women with histories of recurrent abortion who have low-positive IgG anticardiolipin or low- or moderate-positive IgM anticardiolipin results may not be justified. The latter statement is made because, in this study of largely healthy women, IgG or IgM anticardiolipin results at levels just cited were rarely associated with adverse pregnancy outcome. This does not exclude the possibility, however, that a low-positive anticardiolipin test result plus other, yet to be identified factors can combine to cause pregnancy loss and that this adverse combination can be ameliorated with immunosuppressive therapy. However, the latter postulate provides little basis for aggressive treatment. Finally, we recommend that the anticardiolipin test be ordered primarily when there is a high index of suspicion, on the basis of clinical presentation, that a patient has the antiphospholipid syndrome. Women with histories of unexplained pregnancy loss (particularly if this occurred in the second or third trimester), deep vein thrombosis, or stroke and all pregnant women with systemic lupus erythematosus should be screened for anticardiolipin antibodies. 12, 23 Treatment should be considered if the IgG anticardiolipin test result is moderate to high positive or the lupus anticoagulant test result is positive.

We thank Ms. Carrie Marcell for entering and analyzing patient data, Ms. Cathy Head for performing anticardiolipin determination on patient sera, and Dr. Silvia Pierangeli for interviewing patients on follow-up visits and for supervision of anticardiolipin testing.

The effect of maternal cocaine use on the fetus: Changes in antepartum fetal heart rate tracings

Bannie L. Tabor, MD, Alex R. Soffici, MD, Toni Smith-Wallace, LVN, and M. Lynn Yonekura, MD

Torrance, California

Fetal heart rate tracings of pregnancies complicated by cocaine use were analyzed to evaluate the effects of subacute maternal cocaine use on the fetus. Nonstress tests were performed twice weekly on patients from the perinatal substance abuse clinic with screening of maternal urine samples for cocaine, amphetamines, phencyclidine, and opiates at the time of each examination. Nonstress tests performed when the urine toxicology screen was positive for cocaine alone (positive cocaine nonstress tests) were paired with those from the same patient but performed when the screen was negative (negative cocaine nonstress tests). The nonstress tests were analyzed with the Lyons scoring system, which evaluates the baseline heart rate, the oscillatory amplitude of the baseline, the oscillatory frequency, decelerations, and accelerations. Twenty pairs of nonstress tests from 20 patients were analyzed. The total score was higher on the negative cocaine nonstress test in 70% of the pairs and equal in the remaining 30% (p < 0.001). Significant differences occurred in the oscillatory amplitude (p < 0.001), frequency (p = 0.002), and acceleration scores (p = 0.03) but not the fetal heart rate baseline or the deceleration scores. The observed changes may reflect alterations in fetal central nervous system neurotransmitters and fetal state regulation, which may affect the developing central nervous system of cocaine-exposed fetuses and in turn play a role in the developmental and behavioral abnormalities observed in cocaine-exposed infants. (AM J OBSTET GYNECOL 1991;165:1278-81.)

Key words: Cocaine, nonstress test, fetal behavioral states

Cocaine, a potent local anesthetic, inhibits the presynaptic uptake of neurotransmitters such as norepinephrine and dopamine, resulting in a relative excess of these agents in the synaptic cleft. The most notable physical manifestations, tachycardia, arrhythmias, peripheral vasoconstriction, and hypertension, result from cardiovascular stimulation caused by this neurotransmitter excess.2 The euphoric and addictive qualities of cocaine are thought to be secondary to the effects on central nervous system neurotransmitters.3 Long-term cocaine use during pregnancy has been associated with numerous adverse perinatal outcomes, such as intrauterine growth retardation, preterm delivery, abruptio placentae, and congenital anomalies. 4-6 The presumed etiology is repetitive hypoxic insults to the fetus and the placenta as a result of cocaine-induced uterine artery vasoconstriction.5,7,8 Whereas numerous studies have dealt with the effects of long-term cocaine use during pregnancy, few clinical investigations have directly examined the short-term effects of maternal cocaine use on the fetus. To address this question, we analyzed the fetal heart rate (FHR) tracings of pregnancies complicated by cocaine use.

Material and methods

Nonstress tests (NSTs) were performed twice weekly on patients from the Harbor-University of California, Los Angeles, Medical Center perinatal substance abuse clinic beginning at 30 weeks' gestation, as part of the clinic protocol. Maternal heart rate and blood pressure were measured with the patient in the left lateral position at the beginning of the examination. The fetal acoustic stimulation test, with a model 5C electronic artificial larynx (Western Electric, New York), as described by Smith et al.,10 was performed if no spontaneous accelerations occurred within the first 5 to 10 minutes. Maternal urine samples were obtained at the time of each examination and were screened for cocaine, amphetamines, phencyclidine, and opiates with the enzyme multiplied immunoassay technique (E.M.I.T. D.A.U. assay, Syva, Palo Alto, Calif.). NSTs performed when the urine toxicology screen was positive for cocaine alone were designated as positive cocaine NSTs, and those performed when the screen was negative were designated as negative cocaine NSTs. The first positive cocaine NST obtained was paired with the closest chronologically available negative cocaine

Table II. Cardiovascular parameters

	Negative cocaine NST	Positive cocaine NST
No.	20	20
Maternal heart rate (beats/min)	79.1 ± 1.5	80.8 ± 2.1
Maternal mean arterial pressure	73.5 ± 1.2	67.9 ± 3.0
FHR (beats/min)	133.7 ± 1.8	134.6 ± 1.7

NST from the same patient. Each NST was graded with the Lyons scoring system (Table I) by one of the authors (B.L.T.), who was blinded to the identity of the patient and the results of the screen. The Lyons scoring system assigns numeric values (0, 1, or 2) to five parameters on the NST: the baseline heart rate, the oscillatory amplitude of the baseline, the oscillatory frequency, decelerations, and accelerations, with the lower scores assigned to the more abnormal findings.11 The scores for the paired NSTs were compared for both the total and the individual parameters. Gestational age and cardiovascular data are presented as mean ± SEM. Statistical analysis of the paired scores was performed with the Wilcoxon signed-rank test and McNemar's test of symmetry. Cardiovascular and gestational age differences were analyzed with the Student paired t test. Statistical significance was accepted with p < 0.05.

Results

Twenty pairs of NSTs from 20 patients were analyzed. There were no differences in maternal heart rate or blood pressure or in FHR between the positive and negative cocaine NSTs (Table II). There were no episodes of maternal tachycardia or hypertension and no fetal tachycardia in either group. The mean gestational age was 35.9 ± 0.6 and 36.1 ± 0.6 weeks for the negative and positive cocaine NST groups, respectively. The mean time between paired tests was 6.7 ± 1.1 days, with the negative cocaine NST occurring first in 11 pairs and the positive cocaine NST first in nine pairs. None of the patients had underlying medical illnesses, such as diabetes, hypertension, or collagen vascular disease, and none had preeclampsia, abruptio placentae, or intrauterine growth retardation or were delivered postdates (>42 weeks' gestational age).

The total score was higher on the negative cocaine NST in 70% of the pairs and equal in the remaining 30% (p < 0.001) (Fig. 1). When three points was used as a more clinically significant difference, indicating involvement of two or more parameters, 35% of the pairs had higher negative cocaine NST scores (p < 0.01). Among the individual parameters, significant differences occurred in the oscillatory amplitude (p < 0.001), frequency (p = 0.002), and acceleration scores (p = 0.03) but not the FHR baseline or the deceleration scores. Seventy percent of the pairs had higher amplitude scores on the negative cocaine NSTs, whereas higher frequency scores occurred on the negative cocaine NSTs in 55% of the pairs. None of the pairs had higher scores on the positive cocaine NSTs on either of these parameters. Thirty percent of the pairs had higher acceleration scores on the negative cocaine NSTs, whereas only 5% had a higher score on the positive cocaine NST. All three of these parameters were affected on the positive cocaine NST in 25% of

NUMBER OF POINTS NST SCORE WAS LOWERED WITH POSITIVE COCAINE SCREEN

Fig. 1. Magnitude of depression of Lyons NST scores associated with cocaine use. In 70% of patients NST score when urine toxicology screen was positive for cocaine was lower than when screen was negative (p < 0.001). In 35% of patients positive cocaine NST score was \geq 3 points lower than negative cocaine NST scores (p < 0.01).

the pairs, whereas none of the negative cocaine NSTs had all three variables involved (p < 0.05). Twenty percent of the positive cocaine NSTs were nonreactive, compared with none of the negative cocaine NSTs (p < 0.05).

Comment

The finding of lower scores on the NSTs obtained when the urine toxicology screens were positive for cocaine suggests that episodic cocaine use may have adverse consequences for the fetus. The differences observed between the positive and negative cocaine NSTs are probably not short-term hypoxic effects caused by uterine artery vasoconstriction. There were no discernible maternal or fetal cardiovascular changes (tachycardia or hypertension) at the time of the examination; therefore one would expect a similar absence of short-term effects on the uterine vasculature. The positive urine toxicology screens may represent use within the past 1 to 2 days, the period that cocaine metabolites are excreted in the urine and detectable by the present technology.12 If the patient were to be examined in closer proximity to the time of use, the maternal and fetal cardiovascular changes occurring with cocaine intoxication might be seen.

The changes seen in the positive cocaine NSTs, predominantly smaller, slower fluctuations of the baseline with fewer accelerations, are suggestive of the heart rate pattern seen during quiet sleep, or what has been described as fetal behavioral state 1F.¹³ Whereas the heart rate pattern is only one of the parameters used to characterize fetal states and there is some controversy whether true behavioral states exist before 36 to 38 weeks, the differences observed between the positive and the negative cocaine NSTs suggest cocaine-induced perturbations in FHR regulation, if not actual fetal state regulation.14 The regulation of fetal behavioral states is rather complex.15 Various areas in the central nervous system are involved and are sensitive to alterations in neurotransmitters such as serotonin, dopamine, and norepinephrine. Agonists or antagonists of these agents not only may acutely alter activity states but may cause prolonged disruption in state regulation. Clonidine, which blocks the presynaptic release of norepinephrine, has been shown to have immediate effects on electrocortical activity, fetal breathing, and heart rate variation and to cause rapid, irregular cycling of these activities for several hours after injection.16 Whereas cocaine results in the opposite effect on synaptic cleft norepinephrine levels, it too may have prolonged effects on the central nervous system centers responsible for state regulation. In addition, potent metabolites of cocaine, such as norcocaine, may be excreted into the amniotic fluid and recirculated in the fetal environment, causing central effects long after the initial maternal cocaine use.

Neonates exposed to cocaine in utero have been noted to have difficulties in behavioral state regulation and orientation, even if by history maternal use was limited to the first trimester.¹⁷ Hume et al.,⁹ using ul-

trasonography and FHR examination to investigate fetal state regulation, noted similar behavioral state disorganization in 65% of 20 cocaine-exposed fetuses followed up throughout the pregnancy, which correlated with difficulties in neonatal state regulation. Chasnoff et al.17 proposed that cocaine, by altering central nervous system neurotransmitters during embryologic development, behaves as a neurobehavioral teratogen. Because alterations in neurotransmitters during the sensitive stage of structural development in the first trimester probably will have some effect on later function, one cannot downplay the consequences of repetitive disruptions in the developing regulation of fetal behavioral states caused by cocaine use in the third

In summary, analysis of FHR tracings with and without recent exposure to cocaine demonstrates adverse changes with maternal cocaine use. These changes may reflect alterations in fetal central nervous system neurotransmitters and subsequently fetal state regulation, which may affect the developing central nervous system of cocaine-exposed fetuses. This may in turn play a role in the developmental and behavioral abnormalities observed in these infants. Further investigation may more fully characterize this relationship and provide insight into the normal regulation of fetal arousal states and the role that this plays in normal development.

Qualitative evaluation of uterine contractions recorded by a double guard-ring tocodynamometer

Masahiro Shinmoto, MD, Tatsuhiko Kawarabayashi, MD, Masahiko Ikeda, MD, and Hajime Sugimori, MD

Saga, Japan

Qualitative characteristics of uterine contractions in various labors were evaluated by a double guard-ring tocodynamometer, according to the percentages of concurrent and synchronous contractions of two contraction curves when compared with overall contractile activity. For term and preterm labors, percentages of both concurrent and synchronous contractions were significantly higher than those of Braxton Hicks contractions; however, the concurrent and synchronous percentages of preterm labor were lower than those of term labor. Synchronous percentage in groups under maintenance therapy or active treatment in preterm labor were nearly the same; however, the percent concurrent under maintenance therapy was significantly lower than that during active treatment. Both concurrent and synchronous percentages were significantly higher during the active phase of labor than those during the latent phase. The percentages in the latent and active phases of spontaneous contractions were nearly the same; however, they increased significantly during the active phase of augmented contractions, as compared with the latent phase. When the percentages of concurrent and synchronous contractions at each cervical dilatation were retrospectively examined, both values increased significantly between 5 and 6 cm of cervical dilatation. The results suggest that this method can provide important information for understanding the quality of the contraction if attention is paid to the percentages of concurrent and synchronous contractions of two contraction curves and will aid in determining whether oxytocin or tocolysis should be given in term or preterm labor. (AM J OBSTET GYNECOL 1991;165:1282-6.)

Key words: Uterine contraction, guard-ring tocodynamometer, synchronization

The external tocography obtained from a guard-ring tocodynamometer has an advantage over the internal method for recording uterine contractions in obstetric practice because it does not require intrauterine manipulation and can therefore be easily used at any time, even in the second trimester of pregnancy. For these reasons, the external method is widely used for antepartum contraction monitoring, in the same manner as intrapartum monitoring, to judge preterm labor and the effect of tocolytic agents. Typically three patterns of contractions are observed: small contraction, the duration of which is ≤30 seconds; normal contraction wave, lasting about 60 seconds; and long contraction, lasting >3 minutes. Recently, we reported on the clinical features of the small contraction wave.1 In this report small waves were frequently observed when large contractions were suppressed by intravenous β_2 -stimulant infusion for the treatment of preterm labor.1 The long contraction wave that has been reported as resulting from hyperstimulation by oxytocics is sometimes

observed even in cardiotocography of normal pregnant women.2 However, the significance of the amplitude of contractions recorded by the guard-ring method in preterm or term labor has not yet been clarified. Therefore in a preliminary report we focused our attention on the synchronization of contractions at two points of the uterus recorded by small guard-ring tocodynamometers and attempted to elucidate other properties of contractions, in addition to duration and frequency, in routine obstetric practice.3 In that study the conduction of contractions between fundal and caudal regions of the uterus appeared to occur in both directions (i.e., downward or upward). Moreover, the synchronization of ascending points of the lower fifth, between baseline and peak point, of the contraction waves and of the peak points was significantly higher in the active phase than in the latent phase of labor.3

In this investigation, with a new device that can record two traces of fetal heart rate, fetal movements, and. two contraction curves simultaneously, we have attempted to evaluate quality differences of various contractions by monitoring two contraction curves recorded simultaneously in preterm or term labor.

Material and methods

One hundred twenty-four patients from 27 to 41 weeks of gestation were examined in our department at Saga Medical School from April 1988 to June 1989.

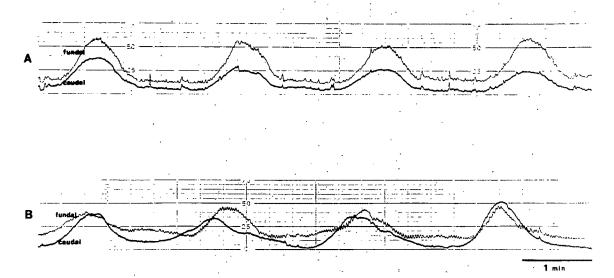

Fig. 1. Actual traces of uterine contractions recorded by double guard-ring tocodynamometer. *Thin line* was recorded from fundal part of uterus and *thich line* from caudal part. **A,** Typical synchronized contractions; **B,** asynchronous pattern.

The patients included 51 nulliparous and 73 multiparous women. Multiple gestations were not included in this study. Height and weight of the patients ranged from 145 to 173 (mean, 156.7) cm and 44.0 to 78.5 (mean, 59.4) kg, respectively. The period of gestation was calculated from the date of the last menstrual period and was confirmed with serial ultrasonographic measurements of crown-rump length and biparietal diameter. All cardiotocograms were obtained by the new device (Toitu Multiactocardiograph MT-430, Toitu Co. Ltd., Tokyo) attached with two small guard-ring tocodynamometers, 3.5 cm in diameter. The pregnant women were placed in the supine or semi-Fowler position and were fitted with the tocodynamometers at two different points on the uterus; one was attached to the middle part of the uterine fundus and the other was attached to the caudal part of the uterus at a distance of >15 cm. Two contraction curves were simultaneously recorded on the same sheet. Recording speed was 3 cm/min.

Contractions recorded in the cardiotocograms were divided into three groups, specifically, Braxton Hicks contractions and contractions in preterm or term labor. Braxton Hicks contractions were recorded from term uncomplicated gestations in patients before onset of labor. Threatened preterm labor was diagnosed by the onset of uterine contraction almost every 10 minutes as observed by external tocography in the outpatient department. Cases complicated with preterm labor were divided into two groups: patients receiving maintenance therapy who were treated with bed rest or oral administration of ritodrine hydrochloride (Kissei Pharmaceutical Co., Ltd., Matsumoto, Japan) and those receiving active treatment with a drip infusion of rito-

drine. Term labors included spontaneous and augmented contractions. For the augmentation of labor, the titration method for oxytocin infusion was performed in all cases.

Actual records are shown in Fig. 1. A wave that elevated ≥ 2 mm from the baseline was considered as a contraction curve. Small waves, the duration of which was ≤ 30 seconds, were excluded from this study. Total contractions refers to the total number of contractions that were recognized, as mentioned subsequently. Contractions that appeared concurrently in upper and lower curves were counted as one, while lone contractions appearing in either upper or lower curve were also counted as one. The percent concurrent refers to the percent of total contractions that were recognized in the upper (fundal) and lower (caudal) curves simultaneously (Fig. 1, A and B). Contraction curves were considered to be synchronized when the peaks of two

Table II. Concurrent and synchronized percentages in various labors

	No.	Concurrent (%)	Synchronous (%)
Braxton Hicks contractions	116	53	12
Term labors	2874	88	41
Preterm labor	614	78	27
During maintenance therapy	121	52	23
During active treatment	493	85	28

For both concurrent and synchronous Braxton Hicks contractions versus preterm labor—during maintenance therapy and for synchronous preterm labor—during maintenance therapy versus during active treatment, p= not significant. For synchronous Braxton Hicks contractions versus all preterm labor, p<0.05. For synchronous Braxton Hicks contractions versus preterm labor—during active treatment, p<0.025. For all other comparisons, p<0.005.

Table III. Concurrent and synchronized percentages at each phase of term labor

	No.	Concurrent (%)	Synchronous (%)
All contractions	2874	84	41
Latent phase	666	81	30
Active phase	2208	90	44
Spontaneous contractions	1063	85	40
Latent phase	342	85	35
Active phase	721	85	43
Augmented contractions	1811	89	41
Latent phase	324	77	24
Active phase	1487	92	45

Concurrent: For all contractions, latent versus active phase, p < 0.005. For spontaneous versus augmented contractions, p < 0.005. For spontaneous contractions, latent versus active phase, p = not significant. For augmented contractions, latent versus active phase, p < 0.005. Synchronous: For all contractions, latent versus active phase, p < 0.005. For spontaneous, versus augmented, contractions, p = not significant. For spontaneous contractions, latent versus active phase, p < 0.05. For augmented contractions, latent versus active phase, p < 0.005.

such concurrent contractions occurred within 1 mm of each other (Fig. 1, A). Thus percent synchronous refers to the percent of total contractions in the upper and lower curves that were not only concurrent but also synchronized.

The χ^2 test was used to determine the significance of the results.

Results

Table I shows the material and experimental conditions of this experiment. Patients examined totaled 124 cases, including 26 cases before onset of labor, 41 of spontaneous labor, 39 of induction or augmentation cases, and 18 of preterm labor. Monitoring durations ranged from 41 to 243 minutes in each examination, depending on the patients' clinical conditions. In the examined records, about 70% of all contraction waves were accurately measurable (measurable contractions, 72%; measurable period of time, 76%) without intervention of the recording artifacts caused by maternal movements and tocodynamometer detachment, as indicated in the table. Table II shows concurrent and synchronous percentages of various labors. In term and preterm labors, both values were significantly higher than those of Braxton Hicks contractions; however, as shown in Table I, the concurrent and synchronized rates of preterm labor were lower than those of term labor. Preterm labor patients were then divided into two groups, specifically those receiving maintenance therapy and those receiving active treatment, as described in Material and methods. Synchronized values for both groups were nearly identical (23% vs 28%); however, the percent concurrent in patients receiving maintenance therapy was significantly lower than that of the active treatment group (52% vs 85%). Table III shows the concurrent and synchronous percentages for term labors. Both values in the active phase of labor were significantly higher than those in the latent phase. This change in percentages was not observed between the latent and active phases of spontaneous contractions (85% and 35% vs 85% and 43%); however, in augmented contractions both values increased significantly in the active phase as compared with the latent phase (latent phase, 77% and 24%; active phase, 92% and 45%). Considering these results, it can be said in general that concurrent and synchronous percentages increase in the active phase of labor as the labor progresses from the onset. Therefore both values at each dilatation of the cervix were retrospectively examined by comparing the contraction curves of the cardioto-

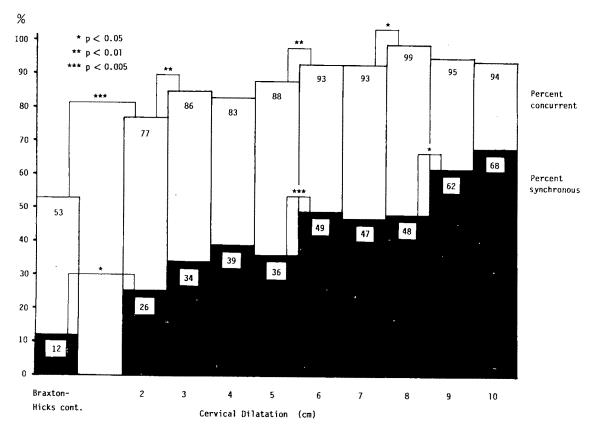

Fig. 2. Concurrent and synchronous percentages at each cervical dilatation in term labor. Statistical significances are represented in figure.

cogram with the corresponding time courses in the partogram of term labor, as shown in Fig. 2. Cervical dilatation was examined every hour and was done more frequently when the labor progressed at a faster rate. From three to 31 contractions were examined at each corresponding dilatation. Consequently, it was found that both values gradually increased with the progress of cervical dilatation. Furthermore, significant differences in the percent concurrent contractions were observed between 2 and 3 cm, 5 and 6 cm, and 7 and 8 cm. On the other hand, significant differences in the percent synchronous contraction were observed between 5 and 6 cm and 8 and 9 cm. Both values significantly increased between 5 and 6 cm of cervical dilatation.

Comment

The guard-ring tocodynamometer, which was invented by Smyth4 in 1957 to enable measurement of the intraamniotic pressure, is indirect and cannot quantitatively measure uterine pressure unless the specific conditions are set. Therefore the amplitude of the contraction curve cannot reveal the exact value of the force of the contraction and cannot be compared with other data. Thus we usually interpret the contraction data recorded by the guard-ring method through pattern recognition with frequency and duration. On the other hand, it is apparent that synchronization of contractions of the myometrial segments in the unicornuate human uterus is one of the most important factors in producing a strong expulsive force. Caldeyro et al.5 proposed these conditions as the optimal set of characteristics of uterine contractility: (1) large absolute intensity of the contractions; (2) strong fundal dominance; (3) good synchronization between the different parts of the uterus; (4) regularity in the rhythm, intensity, and form of the contractions; and (5) during the periods of relaxation, descent of the amniotic pressure to the level of normal tonus. In this study percent concurrent and percent synchronous contractions in term and preterm labor were significantly higher than those of Braxton Hicks contractions (Table II). It can be said that this result reveals the quality difference of each contraction, even if the shape of the contraction curve is the same. The fact that the differences were observed between the latent and active phases of labor (Table III), as reported in our previous article,⁸ also supports the quality difference of the labors. Moreover, the differences between the latent and active phases were more obviously observed in augmented contractions by oxytocin than in spontaneous labor, as shown in Table III. Considering the higher values of both percentages (85% concurrent and 35% synchronous) in the latent phase of spontaneous contractions, more efficient propagation mechanisms for excitation might already be prepared for at the time of spontaneous onset of labor. As for the whole course of delivery, both values gradually increased with the progress of cervical dilatation, as shown in Fig. 2; however, the contraction qualitatively changed between 5 and 6 cm, not between 3 and 4 cm of dilatation, which was described by Friedman⁶ as the turning point of the progress of labor. This result indicates that the turning point of characteristics of the contraction itself may exist between 5 and 6 cm of the cervical dilatation. Clarification of the fundamental mechanism of this change will prove difficult, but it may become an important factor in deciding whether oxytocin is used to augment contraction. In cases of preterm labor, both values were higher than those of Braxton Hicks contractions, especially the percent concurrent during active treatment (Table II). However, both values decreased to the levels of Braxton Hicks contractions, even though active tocolytic treatment was effective. According to these results, examination of both percentages may be useful in deciding whether tocolysis should be continued in cases of preterm labor.

The guard-ring tocodynamometer has many merits

and demerits for the recording of uterine contractions; however, this method can provide important information to understand the quality of the contraction if attention is paid to both concurrent and synchronous percentages, as presented in this study. More data are needed to improve this method in the future.

We are grateful to Professor H. Nakano, Kyushu University, for his valuable advice in this work and also to Mrs. Lisa Tsukamoto for correcting the manuscript.

A prospective, randomized comparison of the Pipelle endometrial sampling device with the Novak curette

Thomas G. Stovall, MD, Frank W. Ling, MD, and Patrick L. Morgan, MD Memphis, Tennessee

This prospective, randomized study compares sample adequacy, pain associated with endometrial biopsy, and correlation of endometrial histologic sampling with hysterectomy histologic results in specimens obtained by the Pipelle (Unimar Inc., Wilton, Conn.) device (N = 149) and the Novak (Miltex, Inc., Lake Success, N.Y.) curette (N = 126). During a 2-year period, patients with abnormal uterine bleeding seen in our ambulatory care facility were enrolled in this trial, unless they did not wish to participate or had a positive pregnancy test result. Patients in both groups were similar with respect to mean gravidity, parity, and menopausal status, although patients in the Novak group were older (43.4 vs 39.1 years, p = 0.005). Patients undergoing Novak biopsy had a mean pain score of 4.36 with 22 of 126 (17%) reporting severe pain, whereas patients undergoing Pipelle biopsy had a mean pain score of 3.21 with only 10 of 149 (6.7%) reporting severe pain (p < 0.05). These pain scores were not affected by menstrual day, gravidity, parity, or menopausal status. Insufficient tissue was reported in 12.8% of patients in the Pipelle group compared with 9.5% in the Novak group (p > 0.05). Fifty patients underwent subsequent hysterectomy. In 48 of 50 (96%), the pathologic results at hysterectomy were in agreement with the histologic findings at endometrial sampling. This clinical trial suggests that Pipelle biopsy appears to be as effective as the Novak curette in obtaining an adequate specimen for histologic analysis and is associated with less pain. (AM J OBSTET GYNECOL 1991;165:1287-9.)

Key words: Endometrial biopsy, Novak curette, Pipelle endometrial sampling device

Endometrial sampling is an important diagnostic tool in gynecologic practice and is used in the evaluation of abnormal uterine bleeding, for endometrial dating, and in the assessment of endometrial histologic results in women receiving hormonal therapy. Traditionally, curettage has been the gold standard sampling technique, although it is being replaced by simpler, less morbid, and less expensive office biopsy techniques. The Novak (Miltex, Inc., Lake Success, N.Y.) curette and vacuum aspirator have been shown to be as accurate as curettage when endometrial histologic results are compared.2

The Pipelle (Unimar Inc., Wilton, Conn.) endometrial suction curette was developed as a method of endometrial sampling, causing less patient discomfort while obtaining adequate tissue for histologic diagnosis. To date, few comparative trials have been conducted comparing this sampling device with other, proved methods of endometrial sampling.8-9

The purpose of this study is to compare sample adequacy and pain associated with sampling and to correlate endometrial sampling histologic findings, with

hysterectomy histologic results in specimens obtained by the Pipelle and Novak curettes.

Material and methods

During a 2-year period ending February 1990, women with abnormal uterine bleeding seen at the Gailor Clinic, the ambulatory care facility of the University of Tennessee, Memphis, were enrolled in this prospective trial. Only women with a positive pregnancy test result or not wishing to participate were excluded. Patients were randomized according to computer-generated numbers to undergo endometrial sampling with either the Novak curette10 (group 1) or the Pipelle (group 2) endometrial suction curette.

The Pipelle device is made of a clear, flexible polypropylene sheath. It has a blunt, rounded distal tip and measures 23.5 cm in length. It has inner and outer diameters of 2.6 and 3.1 mm, respectively. By withdrawing on the inner piston, a negative pressure is created within the endometrial cavity. The Novak curette is a stainless steel curette with an outer diameter of 5 mm. Serrated edges surround its distal opening. A 10 ml plastic syringe was used to create a negative

The position of the uterus was determined by pelvic examination, and the biopsy was performed after the cervix was exposed and cleaned with a povidone-iodine solution. No premedication was used for any patient. The Novak curette was inserted into the endometrial

Table I. Comparison of demographic data and sampling between Novak and Pipelle groups

cavity and the specimen was obtained from the fundal portion. The Pipelle device was introduced into the endometrial cavity, and the piston was then withdrawn to the full length of the instrument, thereby creating a negative pressure. As the instrument was withdrawn, it was rotated, drawing tissue into the lumen. After the Pipelle device was removed, the tip was cut off and the sample expelled. All biopsy specimens were placed in 10% formaldehyde and sent for tissue processing and staining. The pathologist interpreting the endometrial samples was blinded to the instrument used to obtain the sample.

The patient's age, gravidity, parity, and menstrual history were noted. Outcomes measured included specimen adequacy, i.e., the amount of tissue necessary for the pathologist to make a diagnosis. An adequate sample was defined as one or more pieces of endometrium large enough to determine the gland-to-stroma ratio and endometrial morphologic features. An inadequate sample was defined as consisting only of blood or cervical mucus with fragments of benign endocervix or a large amount of blood with only small fragments of endometrial glands and stroma. In those patients requiring hysterectomy, pathologic findings on endometrial biopsy were compared with endometrial histologic results at the time of hysterectomy.

After the biopsy, the patient was asked to quantify the intensity of any pain experienced during the procedure. Pain was graded on a scale of 0 to 10, with 0 being no pain and 10 being severe pain with cramping.

Statistical analysis was performed with a two-tailed Student t test and two-tailed Fisher's exact test, with a p value of < 0.05 considered significant.

Results

Two hundred seventy-five patients were enrolled in this study, 149 (54.2%) undergoing Pipelle device endometrial sampling and 126 (45.8%) having Novak curette sampling. No uterine perforations or other complications were noted in either group. Table I compares the two groups with respect to patient age, gravidity, and parity. Patients in the Novak group were statistically older (p = 0.005) than those in the Pipelle group. Thirty-six (13.1%) of the patients were postmenopausal. The inadequacy rate in this group of patients was 4 of 18 (22.2%) in the Pipelle group and 5 of 18 (27.8%) in the Novak group. Table I also details the indications for endometrial sampling in the two groups. There were no significant differences between groups.

Patients undergoing Novak endometrial sampling had a mean pain score of 4.36, with 22 of 126 (17%) reporting a pain score of >7 (severe pain) and only 39 of 126 (31%) reporting a score of <3 (minimal pain). Patients undergoing Pipelle endometrial sampling had a mean pain score of 3.21, with 10 of 149 (7%) reporting a pain score of >7 (severe pain), whereas 60 of 149 (40%) reported a pain score of <3 (minimal pain). Patients were further subdivided by menstrual days, gravidity, parity, and menopausal status. Those reporting the least pain were in the Pipelle group during the second menstrual week, whereas those reporting the most pain were characterized by Novak biopsy after the third menstrual week. Although there was a significant difference between the two groups (p < 0.05) with regard to pain induced by biopsy, there was no difference within each group with regard to timing of the biopsy during the menstrual cycle.

The histologic results of the biopsies are outlined in Table II. Although no patient had a failed endometrial biopsy, insufficient tissue for histologic diagnosis was obtained in 19 (12.8%) patients in the Pipelle group compared with 12 (9.5%) in the Novak group (p > 0.05). Patients in whom sufficient tissue for histologic analysis was not obtained subsequently either

Table II. Comparison of endometrial histologic results between Novak and Pipelle groups

had repeat endometrial sampling or underwent curettage. No patient in this group was found to have either endometrial hyperplasia or carcinoma.

Fifty patients underwent hysterectomy subsequent to endometrial sampling, 26 (17%) in the Pipelle group and 24 (19%) in the Novak group. In 48 of 50 (96%) patients, the endometrial histologic results at the time of hysterectomy were in agreement with the endometrial sampling histologic results. The hysterectomy specimens of one patient in each group differed significantly from the biopsy findings. In the Novak group a mixed müllerian tumor was found, whereas endometrial hyperplasia without atypicality was found in the Pipelle group. In both patients endometrial sampling had revealed proliferative endometrium.

Comment

This randomized clinical trial suggests that the Pipelle device is as effective as the Novak curette in obtaining endometrial tissue for histologic evaluation. Both the adequacy and quality of the samples obtained by the two methods appeared similar. The study had a 0.129 power of detecting a difference in inadequacy rates of 12.8% and 9.5% between the Pipelle and Novak groups, respectively. To detect a similar difference at a power of 0.80, a sample size of 1507 patients would be required in each group. Thus no definite conclusion can be made in this regard. Unlike other trials,10 this patient population was made up of 13.1% of women who were postmenopausal. The inadequacy rates in postmenopausal patients were 22.2% and 27.8% in the Pipelle and Novak groups, respectively. In this group of older patients, adequate tissue for histologic analysis was obtained in 27 of 36 patients, thereby eliminating the risk and cost of curettage for these patients. Because the Pipelle has a smaller diameter, there is less difficulty in passing the instrument through the cervix and therefore less pain. The smaller size also allows potential entry into uteri with relative stenotic cervices as seen in some menopausal patients. As a result, the Pipelle device may be a preferable instrument in selected postmenopausal patients.

The Pipelle device was associated with less discomfort than was the Novak curette. This was most likely related to its flexibility and smaller caliber. The Pipelle device can be made more rigid by placing it in the freezer, but in this study the Pipelle devices were not pretreated. Although the women in the Novak group were older, confounding is unlikely to have influenced the findings. When the results were reevaluated to eliminate age bias, the results were not significantly altered. In addition, chance also is an unlikely explanation for this difference. This study had a 0.898 power of detecting a difference in pain score as large as 3.21 versus 4.36. Although previous studies revealed the Pipelle to be well tolerated,4-6 to our knowledge this study is the first to quantify patient discomfort. This decreased pain may be a result of the Pipelle's smaller diameter and flexible tip. There also may be an effect of the age differences found between the two groups.

Two patients had an inaccurate diagnosis made at the time of endometrial biopsy. Because not all patients underwent hysterectomy, it is certainly possible that other lesions were not diagnosed. However, it is important to remember that even curettage does not sample the entire endometrium and will, on occasion, not identify a clinically important lesion. The single-use disposable Pipelle device costs \$6 per unit. The initial cost of the nondisposable Novak curette is \$31. Sterilization and packaging and the purchase of the required syringe are additional costs that are incurred with each use for the lifetime of the Novak instrument. However, because the Novak curette's expected useful lifetime is unlimited, whereas a new Pipelle device must be used for each biopsy, the cost factor favors the Novak curette as the number of biopsies performed increases. In fact, depending on sterilization and packaging costs, the Pipelle device may result in increased costs over the Novak curette. The cost of processing the tissue sample and histologic interpretation is the same for both methods.

Spontaneous preterm birth: A case-control study

Ine de Haas, MD, Bernard L. Harlow, PhD, Daniel W. Cramer, MD, ScD, and Fredric D. Frigoletto, Jr., MD

Boston, Massachusetts

Information on demographic characteristics, life-style, and reproductive, prenatal, and medical history was obtained from the prenatal records of 140 women with a preterm delivery (cases) and 280 women with a term delivery (controls) matched by age. Compared with controls, a greater proportion of cases were nonwhite, never married, and educated <12 years. When logistic regression was used to control for confounding variables, a number of risk factors were found to be associated with an increased risk for preterm delivery: a history of a prior preterm delivery (relative risk, 3.5; confidence interval, 1.6 to 7.8), smoking during the pregnancy (p value test of trends, 0.005), and a prepregnancy weight <61.5 kg (relative risk, 2.0; 95% confidence interval, 1.2 to 3.2). Seven (5%) cases and none of the controls indicated a history of maternal diethylstilbestrol exposure (p < 0.001). A history of prior induced abortion was associated with a modest increase in risk for a spontaneous preterm delivery (relative risk, 1.6; confidence interval, 0.9 to 2.7), and this risk increased with increasing numbers of induced abortions (p value for χ^2 test of trend, 0.02). (AM J OBSTET GYNECOL 1991;165:1290-6.)

Key words: Preterm delivery, case-control study, obstetric history, cigarette smoking, maternal weight

In the United States, preterm delivery, defined as the birth of a fetus before 37 completed weeks of gestation, occurs in about 9% of all single live births and accounts for a large proportion of neonatal morbidity and mortality. Approximately two thirds of all preterm births occur spontaneously after premature labor or premature rupture of the membranes. The remaining preterm births are due to adverse maternal or fetal diagnoses that warrant an early delivery, such as hypertension, antepartum hemorrhage, diabetes, or fetal growth

retardation.³ This report seeks to examine risk factors for spontaneous preterm delivery that could be identified from the prenatal history, and our results are based on a case-control study in which medical records were used.

Methods

Cases were defined as women who were delivered of a live singleton infant between 20 and 37 weeks' gestation and in whom the delivery had been preceded by spontaneous labor or rupture of the membranes without induction for maternal or fetal indications. Cases were selected from all deliveries between Oct. 1, 1988, and March 31, 1989, at Brigham and Women's Hospital. We identified 263 deliveries that started spontaneously before 37 weeks (ICD-9-CM codes 644.2, 658.1, and 658.2). Gestational age at delivery was defined by last menstrual period (LMP) confirmed by clin-

ical examination or ultrasonography. We excluded 14 cases with inadequate criteria to classify them as <37 weeks. Also excluded were 109 women transferred to Brigham and Women's Hospital from surrounding community hospitals since they lacked prenatal information that was comparable to that for nontransferred women. The remaining 140 cases were available for analysis.

Women selected as controls were delivered after spontaneous labor at >37 weeks' gestation by similar standards. They were matched to cases by delivery date (closest preceding or subsequent delivery) and maternal age within 1 year. Women transferred from surrounding hospitals were not eligible and two controls were matched to each case.

Demographic characteristics, life-style variables, and reproductive, prenatal and medical history were obtained through a medical record review. Smoking history pertained to smoking during the current pregnancy as reported at the first prenatal visit. Analyses regarding the effect of a prior miscarriage, induced abortion, or preterm delivery excluded primigravid subjects. The χ^2 test and Fisher's exact probability test were used to compare case-control differences for discrete variables and the Student t test was used for the analysis of continuous variables. Relative risk estimates and 95% confidence intervals were calculated and adjusted for confounding factors by means of unconditional logistic regression. Because of the matching design, conditional logistic regression was used to verify all unconditional logistic regression estimates, and any substantial variations are reported in the results.

Results

Table I shows the distribution of the cases and controls by neonatal outcome. The cases delivered after a mean gestational age of 236 days (33 weeks 5 days) and the controls after 278 days (39 weeks 5 days). The mean birth weight of babies born to mothers who had a preterm delivery (cases) was 2328 ± 714 gm compared with a mean of 3496 ± 446 gm in babies born to mothers at term (controls). A greater proportion of cases were delivered of babies with 1-minute Apgar scores of ≤ 5 and 5-minute Apgar scores of ≤ 7 . Ten preterm babies died before discharge from the hospital; six of them had a gestational age <26 weeks. None of the babies of the controls died before discharge. The ratio of boys to girls was 1.33 for the cases and 1.22 for the controls (p = 0.72). Among cases, 12 babies had a congenital malformation (8.6%), compared with 10 (3.6%) babies born to control mothers (p = 0.03). The group of babies with congenital malformations had a variety of diagnoses including minor malformations such as polydactyly and major abnormalities such as trisomy 21 syndrome.

Demographic characteristics of the cases and controls are shown in Table II. A greater proportion of cases were nonwhite, single, and had completed <12 years of schooling. These demographic risk factors are included as adjustment variables in analyses relating to personal characteristics reported below.

A slightly greater proportion of controls than cases were primigravid (31.1% vs 27.9%, Table III). There was no increased risk of a preterm delivery with increasing gravidity or parity (Table III). To examine the

effect of prior pregnancy outcomes, primigravid cases and controls were excluded. The restricted data set showed a similar proportion of miscarriages but a greater occurrence of induced abortions among cases than controls. Women with a history of induced abortions were at a greater risk of a preterm delivery compared with those with no such history, but this was of borderline statistical significance. The relative risk estimates increased with increasing numbers of past induced abortions (*p* value for test of trend, 0.02). A

^{*}Total number varies because of missing information.

history of a preterm birth was reported in 21 (20.8%) of the multiparous cases compared with 14 (7.3%) of the multiparous controls (p < 0.01). This indicates a strong association between a prior preterm birth and prematurity. Compared with women with no history of preterm deliveries, women with one prior preterm delivery and women with two or more prior preterm deliveries had a 2.7-fold and 6.7-fold risk of subsequent preterm delivery, respectively.

Table IV indicates that cigarette smoking during the index pregnancy was associated with a relative risk for preterm delivery of 1.6 (95% confidence interval, 0.9 to 2.9). The relative risk estimates of a preterm delivery increased with increasing number of cigarettes smoked per day (p value for test of trend, 0.005) with the greatest risk in women who smoked >10 cigarettes per day during pregnancy.

Cases and controls were similar with respect to height, whereas the mean prepregnancy weight was substantially less in cases than in controls (Table V). This persisted after additional adjustment for smoking (relative risk, 2.0; 95% confidence interval, 1.2 to 3.2). When a ratio of weight to height (Quetelet's index) was calculated and stratified by mean tertiles within the control group, we observed an increase in risk with decreasing weight-to-height ratios (p value for test of trends, 0.06).

Table VI shows the two-way interaction of maternal weight and cigarette smoking. Compared with nonsmokers who were ≥61.5 kg, nonsmokers who weighed less had a 2.1-fold increase in risk. Smokers in the same weight categories also showed a twofold increase in risk. The greatest risk for a preterm delivery was observed in underweight women who also smoked.

Table VII shows the distribution of a number of medical and gynecologic conditions among the cases and controls. Our case group of spontaneous preterm deliveries excluded cases in which labor was induced because of medical conditions; therefore no significant difference in the frequency of diabetes, asthma, chronic hypertension; and mitral valve prolapse was observed in this study. No significant differences were noted in

Comment

Several studies have described risk factors associated with a preterm delivery. ⁴⁻⁶ The interpretation of these studies is complicated by the fact that some studies did not distinguish between spontaneous preterm births and induced preterm births and by the fact that definitions of prematurity may vary. In the past the definition of prematurity was based solely on a birth weight <2500 gm or was in conjunction with a gestational age of <37 weeks. In 1980, the World Health Organization recommended that a preterm infant be defined as one delivered at <37 weeks' gestation, regardless of weight.⁷ In spite of these limitations, a comparison of the findings from previous studies and our study is instructive.

A number of demographic variables including age, race, and socioeconomic status have been identified as risk factors for prematurity. Two studies have identified an inverse relationship between the age of the

woman and risk of spontaneous preterm birth.8,9 We chose to control for age by matching cases and controls within I year and hence cannot comment on age as a risk factor per se. We found that nonwhite women had an approximately 60% greater likelihood of delivering a premature infant compared with white women. This is in agreement with the study by Henderson and Kay¹⁰ that assessed gestation and birth weight in a group of black women and a group of white women who were similar in socioeconomic status, educational level, age, smoking, amount of prenatal care, and sex of the fetus. They observed that black infants had a significantly shorter gestation and lower birth weight than white infants. Lower socioeconomic status, as defined by a number of indices, also increases the risk of spontaneous preterm delivery.8, 9 In our study unmarried women who had not completed high school had a greater risk for a spontaneous preterm delivery compared with married women who were high school graduates. Clearly, these demographic risk factors must be taken into consideration when other, more easily modifiable risk factors are examined.

We found a modest increase in risk for spontaneous

[†]Restricted to ever-married women.

[‡]The results from the Papanicolaou smear taken at the first prenatal visit were divided into three groups: (1) presence of dysplasia, (2) atypical changes (atypical benign or atypical squamous), and (3) infectious features (inflammation, polymorphonuclear leukocytes, trichomonas, clue cells, or koilocytosis).

preterm delivery associated with a prior induced abortion that was of borderline statistical significance after controlling for demographic factors and gravidity. The effect of induced abortions has been examined in several studies.11,12 As reported by Levin et al.,13 a greater risk for spontaneous preterm delivery was found after two or more induced abortions. Berkowitz9 also found an increased risk for spontaneous preterm deliveries associated with induced abortion, particularly for second-trimester abortions. Our results confirm the observation by Levin et al. and suggest that women with two or more induced abortions have a twofold risk for preterm delivery. Further study of the effect of induced abortion on risk of preterm delivery is warranted and should focus on additional detail with respect to gestational age and the nature of the procedure (i.e., gestational age at time of procedure and details such as whether laminaria pretreatment was used).

In our study a similar proportion of cases and controls experienced one or more prior spontaneous abortions, defined as a pregnancy loss before 20 weeks of gestation. Earlier studies reported no association with preterm delivery and one or more prior spontaneous abortions during the first trimester. 14, 15 However, the prevalence of a preterm delivery increased substantially in women with a history of one or more spontaneous abortions during the second trimester. 14, 15 We were not able to distinguish first- from second-trimester miscarriages in our data.

The strongest risk factors from the obstetric history that we observed was a history of prior preterm birth noted in 21% of cases and only 7% of controls. This translated into a 3.5 fold-increase in risk for prematurity, which agrees well with the observation of Carr-Hill and Hall, 16 who reported a relative risk of 3.2 for a preterm delivery after one previous preterm delivery and a relative risk of 6.8 when the last two gravidities ended in a preterm birth. In a Norwegian study that included nearly half a million singleton births, similar risks were observed.17

Simpson¹⁸ was the first to report a reduction in birth weight as a result of maternal smoking, and this finding has been confirmed. 19, 20 The risk of a preterm delivery or a low-birth-weight infant increases with greater tobacco use.8.21,22 In our study we found a 60% excess risk for preterm delivery associated with maternal cigarette smoking, and the risk of a preterm delivery rose with increased cigarette smoking per day. Biologic explanations for this association include the nicotine content in tobacco smoke, which can cause constriction of the placental arterial vessels, and the carbon monoxide content in smoke, which can produce hypoxemia of the fetus. Whereas there appears to be substantial epidemiologic and biologic data to support the association between smoking and prematurity, we cannot rule out the possibility that the association of cigarette smoking is confounded by other maternal characteristics. In particular, alcohol consumption, associated with preterm delivery in one study,22 was not examined in this data set because of the absence of consistent information on this variable in the medical records we reviewed.

Our finding of an independent association of preterm delivery with decreasing weight and cigarette smoking confirms the findings of Fedrick and Anderson,8 who reported a decline in the prevalence of preterm deliveries with both increasing weight and decreasing cigarette smoking. An earlier investigator suggested that dietary insufficiencies may be responsible for this association.23 This is a hypothesis clearly in need of further study.

Other gynecologic factors investigated in this study included Papanicolaou smear abnormalities and diethylstilbestrol exposure. Findings such as dysplasia or atypia on the Papanicolaou test done prenatally did not appear to influence risk, although 45% of the cases for whom cytologic results were available showed features of inflammation such as white blood cells, trichomonas, or clue cells, compared with 36% of controls. Further study of cervical infection is warranted because of the growing evidence that vaginal flora plays a role in the pathogenesis of preterm labor.24

Exposure to diethylstilbestrol in utero was identified only in the cases. We found no previous study that linked diethylstilbestrol exposure with spontaneous prematurity, but it is known that diethylstilbestrol exposure has been linked to preterm premature rupture of the membranes.25 We considered the possibility of a recall bias to explain this association because women with preterm birth experience may be motivated to search for likely explanations. However, it is unlikely that this association is explained by the presence of recall bias because only one of the seven women with prior diethylstilbestrol exposure had a history of a preterm delivery. Thus diethylstilbestrol exposure may be a strong, albeit relatively rare, risk factor for spontaneous prematurity.

We believe our findings may have several implications for the prevention of preterm birth. We have confirmed that the demographic profile of the woman who is delivered prematurely includes being nonwhite, unmarried, and less well educated. This provides a target population that is in need of better prenatal care. Smoking is a modifiable risk factor for prematurity that should be more aggressively approached through prenatal counseling and smoking cessation programs. Ascertainment of the obstetric history is extremely important since a prior preterm delivery increases threefold the risk for a future preterm birth. A prior preterm delivery or diethylstilbestrol exposure should prompt a search for predisposing factors such as incompetent cervix. Finally, induced abortion was identified as a possible risk factor, which emphasizes the importance of contraceptive counseling.

N POSTPARTUM ENDOMETRITIS*

AZACTAM delivers more than you're expecting...

- Broad aerobic gram-negative in vitro coverage, including <u>Escherichia</u> <u>coli</u>, <u>Proteus</u> <u>mirabilis</u>, and Enterobacter <u>cloacae</u>.[†]
- Greater than 90% cure rates in combination with clindamycin.¹⁻³
- No time-consuming, costly, routine therapeutic drug monitoring.
- May be used in penicillin-allergic patients.[‡]
- Pregnancy Category B.

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

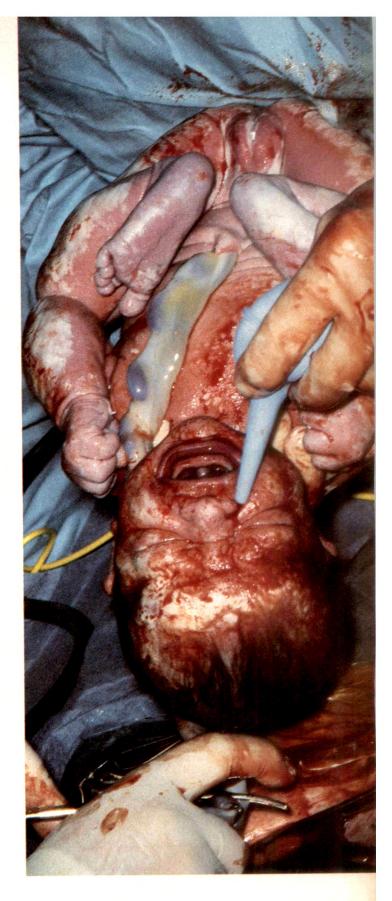

A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the references listed.

Azactam[®] aztreonam IV/IM 1g/2g

A logical alternative to aminoglycosides.

*Due to susceptible organisms.

tAlthough a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.

*Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausealvomiting, and rash.

Please see adjacent page for brief summary of prescribing information.

Azactam[®] aztreonam IV/IM 1g/2g

AZACTAM® FOR INJECTION Aztreonam For Injection

DESCRIPTION-AZACTAM (Aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowishwhite lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gramnegative aerobic pathogens seen in general surgery.

Concurrent Therapy— Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an anti-anaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase in vitro in some gram-negative aerobes such as Enterobacter and Pseudomonas species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These in vitro findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS-Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to lifethreatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents

present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by Clostridium difficile is one primary cause of "antibiotic-associated colitis."

difficile is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against C. difficile (e.g., vancomycin).

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy-Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use-Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: Hypersensitivity—anaphylaxis, angioedema, bronchospasm. Hematologic—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. Gastrointestinal—abdominal cramps; rare cases of C. difficile—associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). Dermatologic—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. Cardiovascular—hypotension, transient ECG changes (ventricular bigeminy and PVC). Respiratory—one patient experienced flushing, chest pain, and dyspnea. Hepatobiliary—hepatitis, jaundice. Nervous System—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. Musculoskeletal—muscular aches. Special Senses—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. Other—vaginal candidiasis, vaginitis, breast tenderness. Body as a Whole—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: <code>Hepatic-elevations</code> of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). <code>Hemic-increases</code> in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. <code>Renal-increases</code> in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION-Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg**, or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231E)

Gynecol 65:825–829, 1985. 3. Henry SA: Overall clinical experience with aztreonam in the treatment of obstetric-gynecologic infections. Rev Infect Dis 7(suppl 4):S703–S708, 1985.

DRUG ABUSE IS CHILD ABUSE

NORPLANT SYSTEM levonorgestrel implants

feel comfortable recommending it to your patients

Effectiveness comparable to tubal ligation

Although no contraceptive is 100% effective, the NORPLANT SYSTEM is one of the most effective forms of birth control ever developed. The average annual gross pregnancy rate over a five-year period is less than 1%.

Lowest expected and typical failure rates with NORPLANT SYSTEM vs. sterilization during first-year use

Adapted from Trussell J, et al.

Long-term convenience... estrogen-free

NORPLANT SYSTEM, a progestin-only contraceptive, is an excellent option for women desiring a long-term method. Its effectiveness lasts for five years and is not dependent on compliance.

Reversible, with prompt return to previous level of fertility

NORPLANT SYSTEM is reversible at any time; the contraceptive effect ceases when the capsules are removed.

In one study, 40% of women wanting to conceive did so within 3 months of removal, 63% by 6 months, 76% by 12 months, and 90% by 24 months.²

High patient acceptance despite menstrual pattern changes

NORPLANT SYSTEM causes menstrual irregularities (the most common complaint), which occur in many women during first-year use and diminish over time. Only 9.1% of patients discontinued during first-year use due to these changes.^{3†}

Women who are thoroughly informed of potential menstrual changes and side effects are more tolerant of them when they occur.⁴

Well-received, well-liked by American women

One study of 140 users revealed that 94% were satisfied with NORPLANT SYSTEM, 91% recommended it to their friends, and 74% wanted to use it again.⁵

A 10- to 15-minute office procedure

A local anesthetic and a small 2 mm incision...little or no discomfort during insertion...proper placement should not leave a noticeable scar...in most cases sutures are not needed.

*Serious as well as minor side effects may occur (see prescribing information).

† Based on multicenter trials of 2,470 women.

Please see brief summary of prescribing information on adjacent page.

Lasts 5 years...yet is reversible

Table II. Five other cases that showed dissociation between serum levels of CA 125 and CA 130

Case No.	Age (yr)	CA 125	CA 130	· Clinical course
1*	42	106	. 14	Adenomyosis
		, 129	24	(after hysterectomy)
2†	43	270	11	NED, 4 yr
3†	55	. 216	9	NED, 4 yr
4†	39	2236	. 6	NED, 5 yr
5†	69	5461	14	NED, 5 yr

NED, No evidence of disease.

except for a small leiomyoma. Interestingly, after removal of the uterus and both ovaries the postoperative serum CA 125 levels increased from the preoperative levels. CA 130 levels measured simultaneously in the sera were consistently low. Therefore a discrepancy between CA 125 and CA 130 levels was observed. The analysis of CA 125 and CA 130 epitopes suggested that the molecule possessing at least two epitopes of CA 125 existed in the sera of this patient, but this molecule lacked the epitopes of CA 130. However, the results of immunohistochemical staining for both CA 125 and CA 130 in the ovarian surface epithelium were positive, implying that both CA 125 and CA 130 existed in the tissues of this patient. Consequently, either the release: mechanism of these epitopes into the serum or the metabolism of these epitopes in the serum may differ in this patient.

Although the exact mechanism of this discrepancy between the serum levels of CA 125 and CA 130 is unclear, this case suggests that healthy women may

rarely have extraordinarily high serum levels of CA 125. Retrospective analysis of CA 125 and CA 130 levels in >2000 women in gynecologic clinics found five patients with high CA 125 levels but low CA 130 levels (Table II). Clinical examinations found no apparent CA 125-producing disorders in those five patients. We have never examined a patient with high CA 130 levels and low CA 125 levels. This implies that CA 130 levels, rather than CA 125 levels, seem to correlate well with pathologic changes in the patients.

[†]Clinical examination did not reveal abnormalities and laparotomy was not performed.

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION. Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Active thrombophlebitis or thromboembolic disorders.
 Undiagnosed abnormal genital bleeding.
 Known or suspected pregnancy.
 Acute liver disease; benign or malignant liver tumors.
 Known or suspected carcinoma of the breast.

- A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

 1. Bleeding Irregularities Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, and amenormee may occur, and could mask symptoms of cervical or endometral cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.
- 2. Delayed Follicular Atresia Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be
- 3. Ectopic Pregnancies Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out extends pregnancy in an extent of pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent pregnancy in any extent present prognancy in any extent pregnancy in any extent pregn
- ectopic pregnancy in any patient presenting with lower-abdominal pain.

 4. Breast-feeding Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after
- Solution.

 5. Foreign-body Carcinogenesis Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.
- OF International Contractors Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

 B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

- Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

 1. Cigarette Smoking Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

 2. Elevated Blood Pressure — Increase in blood pressure has been reported in combination OC
- users; prevalence increases with long exposure.

 3. Thromboembolic Disorders and Other Vascular Problems An increased risk of
- 3. Intromobemobilic Disorders and Other Vascular Problems An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.
 Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hyperatoric hyperatoric handless.

hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is

In thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of

levonorgestrel-containing OCs.

4. Carcinoma — Recent evidence in the literature suggests no association between OC use and

- increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms. 5. Hepatic Tumors — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal
- hemorrhage.

 6. Ocular Lesions Retinal thrombosis is associated with OC use and is believed to be related to 6. Ocular Lesions — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if their sunexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately. 7. Use Before or During Early Pregnancy — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. Galibladder Disease — Early studies reported an increased lifetime relative risk of galibladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

 Physical Examination and Follow-up — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should

bleeding. Women with a strong raminy instory of breast cancer or who have breast flouries should be monitored with particular care.

2. Carbohydrate Metabolism — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See Warning)

Warnings.) 3. Liver Function -- Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. Fluid Retention — Steroid contraceptives may cause some degree of fluid retention. Prescribe

- with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.
- 5. Emotional Disorders Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

 6. Contact Lenses Contact-lens wearers who develop visual changes or changes in lens
- tolerance should be assessed by an ophthalmologist.

 7. Insertion and Removal Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If a capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur over implant site but is usually reversible following removal. See Full Prescribing Information for
- Detailed Insertion/Removal Instructions.

 8. Infections Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.
- 9. Expulsion Expulsion of capsules was uncommon; frequency increased when capsule 9. Expulsion — expulsion or capsules was uncommon; requency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement. Contraceptive efficacy may be inadequate with fewer than 6 capsules.

 10. Provisions for Removal — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of the page of pages.
- of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and trilodothyronine uptake

CARCINOGENESIS: See Warnings section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See Warnings section and Full Prescribing Information.

NURSING MOTHERS: See Warnings section and Full Prescribing Information.

NIFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal. Adverse Reactions

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site – usually transient – (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects – based on 849 removals – (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis, and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Desage and Administration
The NORPLANT SYSTEM consists of six Silastic* capsules, each containing 36 mg of the progestin, levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. (See Full Prescribing Information for Detailed Insertion/Removal Instructions.)

Severe obstructive sleep apnea and associated snoring documented during external tocography

David M. Sherer, MD, Christine B. Caverly, RN, and Jacques S. Abramowicz, MD Rochester, New York

Severe obstructive sleep apnea, a disturbance of sleep resulting from intermittent periodic obstruction of the upper airway, was diagnosed after cardiotocography during which the external tocodynamometer disclosed a pattern initially thought to represent uterine activity. In spite of this obstructive sleep apnea with associated markedly low, hypoxic oxygen saturation levels and daytime somnolence of 10 to 12 hours from 32 weeks until delivery, subsequent fetal outcome was good. (AM J OBSTET GYNECOL 1991;165: 1300-1.)

Key words: Pregnancy, obstructive sleep apnea, cardiotocography

Cardiotocography is a widely accepted mode of monitoring both the fetal heart rate and maternal uterine activity. Artifacts of both components are well documented and include doubling and halving of the fetal heart rate and increased fetal heart rate variability with Doppler ultrasonography systems. The external tocodynamometer, a nonquantitative measure of the duration and amplitude of uterine contractions, may nonintentionally pick up fetal activity, maternal coughing, maternal respirations, or changes in maternal position. We describe an unusual case in which intermittent periods of apnea and labored breathing with associated snoring recorded by external tocography subsequently led to the diagnosis of severe obstructive sleep apnea in pregnancy.

Case report

A 27-year-old obese, white patient with insulin-dependent diabetes mellitus since age 14 was followed up during her first gestation at Strong Memorial Hospital. Ocular cataracts were her only diabetic complication. She was first seen at 12½ weeks' gestation, at which time she weighed 207 pounds. Gestational dating was confirmed by ultrasonography. Glycosylated hemoglobin was 8.4%. Maternal serum α -fetoprotein was elevated at 3.30 multiples of the median, after correction for insulin-dependent diabetes. Ultrasonographic evaluation, including a detailed echocardiogram, disclosed normal fetal anatomy. Amniocentesis revealed an elevated amniotic fluid α -fetoprotein level of 2.6 multiples of the median. Acetylcholine esterase electrophoresis

From the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Rochester School of Medicine and Dentistry.

Received for publication April 25, 1991; accepted May 15, 1991. Reprint requests: David M. Sherer, MD, Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, University of Rochester School of Medicine and Dentistry, Strong Memorial Hospital, 601 Elmwood Ave., Box 668, Rochester, NY 14642-8668. was negative. A balanced chromosomal translocation was identified in all 20 cells analyzed, the fetal karyotype being 46, XY, t(2;14) (p23;q32). Maternal karyotype was normal; paternal karyotype was not obtainable. The blood glucose level was maintained between 80 and 150 mg/dl. Weekly nonstress tests were initiated at 32 weeks' gestation and were reactive. Approximately at this time the patient began complaining of excessive daytime somnolence. Beginnning at 35 weeks' gestation, the patient fell asleep during every nonstress test, and frequent, recurrent apneic episodes of 15 to 20 seconds' duration, followed by labored breathing and loud snoring, were noted. This respiratory pattern was recorded on the external tocodynamometer with the transducer positioned as usual over the maternal abdomen (Fig. 1). By 36 weeks, the patient was sleeping between 10 and 12 hours throughout the daytime and falling asleep in inappropriate situations—during conversations with friends and while smoking cigarettes. Further investigation of the sleep disorder was not possible at this time because of the patient's noncompliance.

At 37 weeks, mild preeclampsia ensued with blood pressure of 140/90 mm Hg, pedal edema (+3), and proteinuria (+3). Ear, nose, and throat examination disclosed a large tongue base, a relatively small pharyngeal arch with a large uvula, hypertrophy of the inferior nasal turbinates, and redundant nasopharyngeal mucosa, associated with obstructive sleep apnea. Ultrasonography demonstrated a vertex-presenting fetus with an estimated fetal weight of 2665 gm and decreased amniotic fluid volume. With an amniocentesis revealing a lecithin-sphingomyelin ratio of 3.3 and positive phosphatidylglycerol, delivery was elected. After failed efforts at intravenous oxytocin induction of labor, during which the patient slept almost continuously with the obstructive apnea pattern, cesarean section was performed while she was under epidural anesthesia. A male infant weighing 2780 gm was delivered with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Umbilical cord arterial pH was 7.28, Po2 was 27 mm

An extraordinarily high CA 125 level in a woman without apparent pathologic foci of CA 125 production: Dissociation between serum levels of CA 125 and CA 130

Fuminori Kobayashi, MD, Shingo Fujii, MD, Hirofumi Nonogaki, MD, Yoshihiko Nanbu, MD,* Toshiko Iwai, MD,* Ikuo Konishi, MD,* Norimasa Sagawa, MD,* Takahide Mori, MD, Masako N. Hosono, MD, and Keigo Endo, MD Kyoto, Japan

We describe a patient with high serum CA 125 levels before and after surgery (>403 U/ml) who had no apparent pathologic foci of CA 125 production. Serum levels of CA 130, which exists on the same glycoprotein as CA 125, were within normal ranges (<35 U/ml) before and after surgery. (AM J OBSTET GYNECOL 1991;165:1297-9.)

Key words: CA 125, CA 130

Recent monoclonal antibodies 130-22 and 145-9 have been reported to recognize the epitope of CA 130, which exists on the same glycoprotein as CA 125.1.2 CA 130 levels correlate well with CA 125 levels in both sera and various tissues, and the coefficient correlation is 0.98.1.2 Moreover, the staining for CA 130 correlates well immunohistochemically with that of CA 125. However, we recently encountered a woman with extraordinarily high serum CA 125 levels who had no apparent pathologic foci of CA 125 production and whose serum CA 130 levels were always within normal ranges.

Case report

A 51-year-old gravida 4, para 2 menopausal woman participating in a whole-body-check program was found to have a high CA 125 level (403 U/ml; normal level <30 U/ml). The whole-body check included a pelvic and abdominal computed tomography scan and demonstrated no other abnormalities. The patient had no history of gynecologic diseases. Magnetic resonance imaging revealed a myomatous nodule (3 cm in diameter) in the myometrium, with no other abnormalities in the pelvis. Vaginal cytologic test, hysteroscopy, chest x-ray examination, peripheral blood analysis, serum chemistry studies, and other tumor markers (carcinoembryonic antigen, CA 19-9, and α-fetoprotein) were within normal ranges. The CA 125 level, measured with a CA 125 radioimmunoassay kit (Centocor Inc., Malvern, Pa.) was 805 U/ml. In contrast, the CA 130 level, measured in the same serum sample with a

U/ml o CA125 CA130 2000 1500 1036 1000 500 403 50 40 30-20 10 90 IX X XI IIX I II III IV V VI VII VII IX X

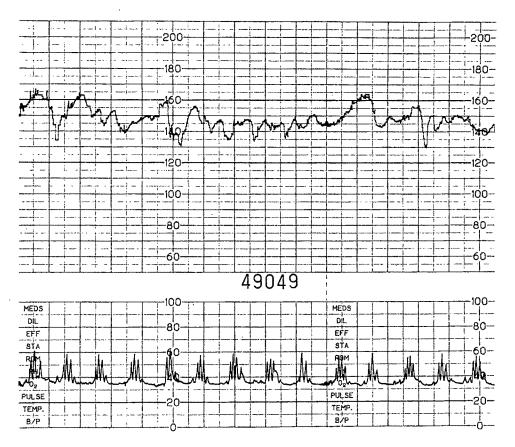

Fig. 1. Cardiotocography at 37 weeks 3 days' gestation. Note frequent regular "uterine activity" subsequently recognized as severe obstructive apnea. Spikes represent labored respiratory movements with snoring. Intermittent straight baseline represents recurrent apneic episodes of 15 to 20 seconds' duration. (Paper speed 3 cm/min.)

Hg, and PCO₂ was 68 mm Hg. The infant's blood glucose level at delivery was 80 mg/dl.

After delivery, an overnight "polysomnogram" (sleep study) showed severe obstructive sleep apnea with oxygen saturation during apnea that generally fell into the low 70% range but occasionally was as low as 63%. The respiratory disturbance index (number of apnea episodes per hour of sleep) was markedly elevated at 144 (normal range, 0 to 5). Treatment with nasal continuous positive airway pressure delivered by nasal mask was not tolerated well by the patient yet elevated the oxygen saturation to 95%.

Comment

The development of severe obstructive sleep apnea in pregnancy, with loud snoring and excessive daytime somnolence, similar to that of our patient has been reported, suggesting that sleep apnea may be either precipitated or exacerbated during pregnancy. It is of interest to note that both these patients had preeclampsia and narrowed oropharyngeal airways with large posterior tongues and redundant pharyngeal mucosa, all contributing factors of upper airway obstruction associated with obstructive sleep apnea. Although both of the reported cases had normal fetal outcomes at

delivery, fetal heart rate decelerations and fetal scalp blood acidosis have been documented during sleep apnea.¹ The long-term effect of recurrent, frequent apneic events on the fetus is unknown. Treatment of this disorder is by either surgical correction of the obstruction or nasal continuous positive pressure delivered by nasal mask.¹

Snoring is known to be associated with a contraction of the abdominal muscles during a substantial part of expiration and an abrupt relaxation of abdominal muscles at the onset of inspiration.² Thus the external tocodynamometer recorded abdominal wall excursion during the snoring with the apneic episode represented by the flat baseline and the labored breathing associated with snoring represented by the elevated baseline and spikes; this is yet another artifact detected by external tocography.

trium. A simple hysterectomy with bilateral salpingooophorectomy was performed. The tumor in the myometrium was histologically confirmed to be a leiomyoma.

Fig. 1 shows the CA 125 and CA 130 levels in the sera of the patient before and after surgery. Serum CA 125 levels were consistently high, and the CA 130 levels were consistently within normal ranges. The patient continues to be well with high serum CA 125 levels after the operation.

To analyze the dissociation between serum CA 125 and CA 130 levels in this patient, we developed four systems of a double-determinant assay using monoclonal antibodies OC 125, 130-22, and 145-9. The sera of a patient with ovarian cancer who had high CA 125 levels were used as positive controls. In the case of ovarian cancer, when the CA 125 level was measured by using iodine 125-labeled OC 125 with 145-9-coated beads, the level became higher than the level measured by using ¹²⁵I-labeled OC 125 with OC 125-coated beads (Table I). Similarly, when the CA 130 level was measured by using ¹²⁵I-labeled 130-22 with OC 125-coated

beads, the level became higher than the level measured by using ¹²⁵I-labeled 130-22 with 145-9—coated beads. However, in the serum of our patient, the CA 125 level measured by using ¹²⁵I-labeled OC 125 with OC 125—coated beads was >500 U/ml, but it was 16 U/ml when measured by using ¹²⁵I-labeled OC 125 with 145-9—coated beads. Moreover, CA 130 levels measured by using ¹²⁵I-labeled 130-22 with OC 125— or 145-9—coated beads were <16 U/ml (Table I).

Examination of frozen sections containing ovarian surface epithelium and leiomyoma tissues revealed positive results of tests for both CA 125 and CA 130 (Fig. 2). However, other constitutive elements of the ovary and leiomyoma showed no staining for CA 125 or CA 130.

Comment

A case of extraordinarily high serum levels of CA 125 without apparent pathologic foci of CA 125 production is presented. An exploratory laparotomy revealed no pathologic changes in the abdominal cavity

Management of fetal hemolytic disease by cordocentesis

II. Outcome of treatment

Carl P. Weiner, MD,^a Roger A. Williamson, MD,^a Katharine D. Wenstrom, MD,^a Susan L. Sipes, MD,^a John A. Widness, MD,^b Stanley S. Grant, RN,^a and Louise Estle, RN *Iowa City, Iowa*

Forty-eight of 128 pregnancies complicated by maternal red blood cell alloimmunization (49%) received a total of 142 intravascular transfusions (range, 1 to 7) for treatment of severe anemia (hematocrit, ≤30%). Thirteen fetuses (27%) had hydrops when therapy was initiated. The overall survival rate was 96%. Eighty-five percent of survivors received two or more transfusions before delivery. The mean gestational age at initiation of therapy was 28 weeks (range, 18 to 36 weeks). Bleeding from uterine and umbilical cord puncture sites was not of clinical significance. The most common complication was fetal bradycardia (8%). Simple intravascular transfuson resulted in the replacement of fetal red blood cells with adult red blood cells and suppression of fetal erythropoiesis. By the completion of the second transfusion, on average, <1% of circulating red blood cells were fetal. Within 3 weeks of the second transfusion, the mean reticulocyte count was <1%. The rate at which the fetal hematocrit declined after a transfusion (exclusive of the first) was inversely related to gestational age (r = -0.84, p < 0.0001), permitting a 4- to 5-week interval between transfusions after 32 weeks' gestation. A total of 78% of surviving neonates were delivered at term. Neonates transfused more than once antenatally required less phototherapy (75.8 \pm 54 vs 165 \pm 101 hours, p < 0.003) and, when delivered at term, fewer hospital days (4.8 \pm 2 vs 8.6 \pm 6 days, p = 0.01) compared with those transfused once. We conclude that the treatment of fetal anemia by intrauterine simple intravascular transfusion permits a term delivery in the majority of cases and is associated with high perinatal survival and low perinatal morbidity. (AM J OBSTET GYNECOL 1991;165: 1302-7.)

Key words: Fetal hemolytic disease, cordocentesis, fetal intravascular transfusion, immune hydrops fetalis, neonatal hyperbilirubinemia

The first wide-scale fetal therapy was intraperitoneal transfusion for the treatment of fetal hemolytic disease, the success of which varied from center to center. Fetal intravascular transfusion replaced intraperitoneal transfusion as the method of choice for the treatment of fetal hemolytic anemia at the University of Iowa in 1985. We report our experience with the treatment of 48 severely anemic (hematocrit, ≤30%) fetuses who were identified using cordocentesis. The findings demonstrate that simple intravascular transfusion to maintain the fetal hematocrit consistently in a near-normal range (1) results in sustained suppression of fetal cryth-

6/1/30439

ropoiesis, (2) is safe enough to routinely allow a term delivery, and (3) is, as a result of the preceding, associated with low perinatal morbidity and mortality.

Methods

Fetuses of alloimmunized pregnant women and in need of transfusion were identified exclusively with cordocentesis, as previously described.1 Transfusion therapy was initiated when the fetal hematocrit was <30%, because this value is well below the 2.5th percentile for the normal fetus ≥20 weeks. Transfusions were performed as a simple infusion of packed red blood cells (70% hematocrit) into the umbilical vein, as previously described.2 Umbilical venous pressure, pH, Pco2, and Po2 were measured and bicarbonate and base deficit were calculated by standard nomograms. The infusion of blood was halted if the pressure rose significantly above normal.3 Because of the duration of the procedure (20 to 30 minutes) and the volume infused (up to 200 ml), each fetus received pancuronium (0.3 mg/kg estimated fetal weight intravenously) to prevent fetal movement and furosemide (3 mg/kg estimated fetal weight intravenously) to maximize venous capacitance immediately before the transfusion. Our goal was a final fetal hematocrit between 45% and 50%. Initially, hydropic fetuses were treated no differently than nonhydropic fetuses. Hydrops was defined as frank anasarca-edema and fluid accumulation in at least two cavities. The transfused blood was negative for cytomegalovirus, hepatitis B, and human immunodeficiency virus; compatible with mother and fetus; buffy coat poor; washed in saline solution to minimize the risk of viral contamination; irradiated to eliminate the risk of graft-versus-host disease; and resuspended in saline solution. Transfusions were initially repeated at 2- to 3week intervals when the hematocrit was anticipated to be between 25% and 30%, assuming a 120-day adult red blood cell lifespan. Frequent transfusions minimized both the duration of fetal anemia and the stimulus for fetal erythropoiesis.

The volume of blood infused was individualized for each fetus. We retrospectively tried several different formulas to estimate the volume necessary but found none were accurate enough. We therefore estimated the required volume on the basis of past experience, infused half the estimated requirement, and then measured the increase in the fetal hematocrit. By knowing the amount by which the hematocrit had increased after the first aliquot of blood, the total volume necessary to reach the desired final hematocrit could be easily calculated. In general, aliquots of 20 ml were used in fetuses <22 weeks, 30 ml for fetuses <26 weeks, 40 ml for fetuses <30 weeks, and 50 ml for fetuses <35 weeks. A transfusion consisted of two aliquots.

Laboratory tests monitored during transfusion included a complete blood cell count (Technicon, Tarrytown, N.Y.) and a Kleihauer-Betke stain to determine the percent circulatory fetal red blood cells. These were performed in the central hospital laboratory. Umbilical venous pH, Pco₂, and Po₂ were measured in heparinized plasma (Instrumentation Laboratory, Lexington, Mass.).

Data were maintained prospectively in a computerized data base. The results are presented as the mean ± SD unless stated. Analyses included paired and unpaired t tests, cross tabulation, and stepwise multiple regression. A $p \le 0.05$ was considered to indicate a significant difference.

Results

Forty-eight fetuses underwent 142 simple intrauterine intravenous transfusions for the treatment of fetal hemolytic anemia. The overall survival rate was 96%. Thirty-seven fetuses (77%) received two or more transfusions (maximum, seven).

The mean gestational age at the first transfusion was 28 ± 5 weeks (range, 18 to 36 weeks). The mean hematocrit before the first transfusion was 20% ± 8%

(range, 4% to 30%). In subsequent transfusions, the mean hematocrit before the procedure was $27\% \pm 6\%$. The mean volume of packed red blood cells administered was 81 ± 38 ml (maximum, 200 ml). The mean hematocrit at the end of the transfusion was $47\% \pm 5\%$. No transfusion attempt was unsuccessful.

Thirteen fetuses (27%) were hydropic when therapy was initiated. Although the hydrops resolved before delivery in all cases, the time required for complete resolution varied from 48 hours to 6 weeks. There were no deaths among nonhydropic fetuses, and the survival rate for hydropic fetuses was 85% (11/13). After the transfusion of 10 fetuses, the hematocrit was again measured 24 to 48 hours later. In all instances, this second hematocrit was within 3% of the final hematocrit obtained on completion of the transfusion.

Our practice was strongly affected by our early experiences. The first fetus transfused was delivered electively at 35 weeks, I week after its first transfusion. This neonate experienced severe hyperbilirubinemia in spite of multiple, double-volume exchange transfusions and is deaf. This episode strengthened our resolve to achieve a term delivery whenever possible. There were no other elective, preterm deliveries of treated fetuses.

Two hydropic fetuses died shortly after the first transfusion. Both of these cases led to a change in management. The first was an acidotic (umbilical venous pH = 7.31 before transfusion, 2 SDs from the norm = 7.39), hydropic 22-week fetus treated early in our experience (transfusion No. 26). The hematocrit was increased from 5% to 45%. One hour after the technically uneventful transfusion, a bradycardia developed and the fetus died shortly thereafter. There was no evidence of umbilical cord trauma at delivery 24 hours later. We assumed this death was secondary to volume overload, although we had not monitored intravascular pressure. We therefore added umbilical venous pressure measurement to our protocol for all subsequently treated fetuses.

We have recently come to believe that transfusionrelated acidemia also may be a factor in the death of the hydropic fetus. This impression originated with our second loss but was supported by the first. Although the umbilical venous pressure of this acidotic (umbilical venous pH = 7.34) 25-week fetus remained stable during the transfusion and the heart rate was normal, the acidemia became profound (umbilical venous pH = 7.26). A bradycardia developed 10 minutes after the transfusion was completed and did not recover; the fetus died. In light of preexisting symptomatic maternal respiratory compromise (chronic lung disease) and the moribund state of the fetus, an emergency cesarean section was not performed. There was no evidence of umbilical cord trauma at delivery 48 hours later.

We then modified our protocol for the first trans-

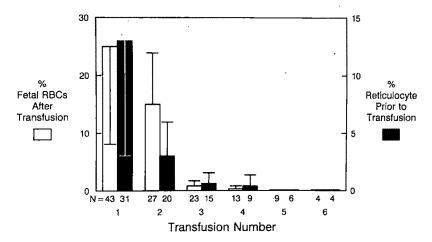

Fig. 1. Effect of intravascular transfusion on fetal reticulocyte count (percent before transfusion) and percent circulating fetal red blood cells (RBCs) (after transfusion) as estimated with Kleihauer-Betke stain.

fusion of hydropic fetuses to minimize the risks of volume overload and acidemia. The anemia is corrected in two steps 24 to 48 hours apart. The hematocrit is increased to approximately 25% (if the umbilical venous pressure is acceptable) during the first step and to 45% to 50% during the second step. Should the umbilical venous pH decline below 7.30, we infuse 4.2% sodium bicarbonate in 1 ml aliquots and recheck the pH 5 minutes later. The acidemia in three hydropic fetuses with a decline in umbilical venous pH <7.30 during transfusion has since been successfully treated with this protocol.

There were two nonlethal other complications directly related to the transfusion. In one woman whose fetus was seen initially with hydrops at 18 weeks, Staphylococcus epidermidis amnionitis developed several days after a transfusion performed at 25 weeks. She was delivered after intractable preterm labor. One woman was delivered at 35 weeks' gestation on an emergency basis because of a prolonged fetal bradycardia after inadvertent puncture of the umbilical artery before the transfusion was initiated. Puncture of the umbilical artery is a recognized risk for fetal bradycardia.4 These children are alive and well (18 and 43 months of age, respectively, at submission of manuscript). The overall incidence of bradycardia was 8%. Except for the one episode leading to cesarean delivery and the two described episodes associated with fetal death, each resolved within 10 minutes. All neonates who experienced a bradycardia and survived are said to be developing normally by either the pediatrician or a parent.

There were five obstetric complications not temporally related to transfusion. Three women experienced preterm premature rupture of membranes followed by preterm labor 1 and 3 weeks after the last of several transfusions. Two growth-retarded fetuses were deliv-

ered because of abnormal results of heart rate testing 2 to 3 weeks after the last transfuson. These five deliveries each occurred between 32 and 36 weeks and were associated with an uneventful neonatal course.

Simple intravascular transfusion was well tolerated by the fetus. Because the infused blood was acidotic (pH, 6.9 to 7.0), umbilical venous pH declined (7.40 \pm 0.02 to 7.35 \pm 0.03, p < 0.0001) during the transfusion. Severe fetal acidosis necessitating bicarbonate was seen only in fetuses with a hematocrit \leq 15%. Transfusion improved fetal oxygen delivery by increasing hematocrit; the umbilical venous PO₂ remained stable (39 \pm 7 to 40 \pm 6 mm Hg, p = 0.16).

In spite of the fairly large intravascular volume load, the umbilical venous pressure (corrected for amniotic fluid pressure) of nonhydropic fetuses rose only 5 ± 4 mm Hg (p < 0.0001) over baseline (range, 0 to 13 mm Hg). It remained within the normal range (<10 mm Hg) during 69% of procedures. Four of the five hydropic fetuses in whom umbilical venous pressure was measured had an elevated pressure before the first transfusion (range, 11 to 15 mm Hg). In three, the umbilical venous pressure rose abruptly (10 to 12 mm Hg) in spite of limiting the volume transfused to an amount adequate to raise the hematocrit to between 25% and 30%. When the umbilical venous pressure was measured again in these three fetuses just before the second transfusion 24 to 48 hours after the first, it had declined to a mean of 6 mm Hg (p = 0.07) and remained in the normal range throughout the second transfusion. In the remaining two hydropic fetuses studied, the umbilical venous pressure declined into the normal range during the course of the first transfusion. This sustained decline was not observed in any nonhydropic fetus.

The fetal reticulocyte count dropped after the ane-

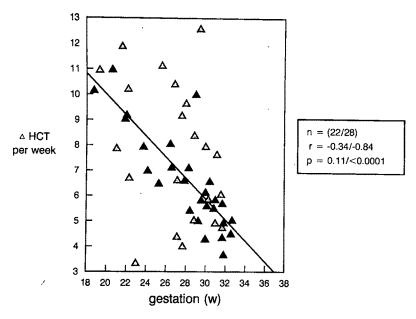

Fig. 2A. Effect of gestational age on decline in hematocrit after transfusion. *Open triangles*, Decline in hematocrit between first and second transfusions; *closed triangles*, decline for all subsequent transfusions. Regression line is based on all subsequent transfusions. *HCT*, Hematocrit.

mia had been corrected by transfusion. Within 3 weeks of the second transfusion, the mean reticulocyte count was <1% (Fig. 1). In addition, the percentage of circulating fetal red blood cells by the conclusion of the third transfusion was <1% (Fig. 1).

To determine with greater precision how often transfusions should be repeated, we calculated the rate the fetal hematocrit declined between transfusions performed January 1985 to October 1989 (32 fetuses, 91 transfusions) by subtracting the pretransfusion hematocrit from the final hematocrit of the previous transfusion and dividing the result by the intervening weeks. There was an inverse relationship between the rate the hematocrit declined and the gestational age at which the transfusion was performed (Fig. 2A). The scatter was quite wide for the decline in hematocrit per week between first and second transfusions (r = -0.34, p = 0.11). However, the correlation between hematocrit decline and gestational age for all subsequent procedures was very good (r = -0.84; p < 0.0001; standard error of the estimate 1.082). Fetal blood contributed minimally to the hematocrit after the second transfusion; therefore a differing rate of hemolysis for different populations of red blood cells cannot account for the close relationship between hematocrit decline and gestational age.

The relationship between gestational age and the rate of hematocrit decline was confirmed prospectively in the next 13 transfusions performed between November 1989 through mid-January 1990. The rate of decline in hematocrit between procedures closely approxi-

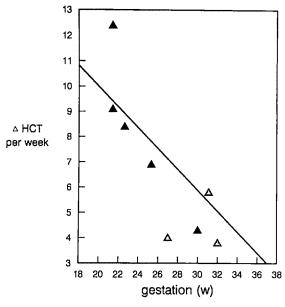

Fig. 2B. Prospective confirmation of relationship shown in Fig. 2A with new data. *Open triangles,* Decline in hematocrit between first and second transfusions; *closed triangles,* decline for all subsequent transfusions. Regression line is from Fig. 2A. *HCT,* Hematocrit.

mated the regression line obtained for the first data set (Fig. 2B). The gestational age influence on the rate of hematocrit decline after the second transfusion required a 2- to 3-week interval between transfusions at 20 weeks' gestation while allowing a 4- to 5-week interval after 32 weeks' gestation (assuming similar final hematocrits).

Eight-two percent (36/44) of surviving neonates without heart rate abnormalities associated with growth retardation were delivered at term (Table I). Eleven of the 46 survivors (includes nonelective preterm delivery) (24%) underwent one or more double-volume exchange transfusions. Eight of the 11 required only one exchange. Two of the eight were performed at outside institutions per routine rather than as treatment for hyperbilirubinemia. Simple transfusion for treatment of anemia was performed after discharge in 13 neonates (28%). Each was associated with a delayed return of reticulocytes to the peripheral circulation rather than early neonatal hemolysis.

Neonates transfused more than once antenatally (and therefore delivered at least 9 weeks after transfusion therapy had begun) had a less complicated postnatal course than infants transfused only once (Table II). While not all data were available, they did receive less phototherapy and had a near-significant decrease in the likelihood of receiving a double-volume ex-

change transfusion. When delivered at term, neonates antenatally transfused more than once spent less time in the hospital. The mean peak total bilirubin was lower in term neonates whose reticulocyte count at birth was $\leq 1\%$ (10.8 \pm 6 mg/dl, n=8 vs 15.8 \pm 6 mg/dl, n=10; p<0.05). There was a trend toward reduced phototherapy when the amount of circulating fetal red blood cells was $\leq 5\%$ (61 \pm 59 hours, n=13 vs 133 \pm 151 hours, n=5; p=0.08).

As the number of patients with successful pregnancies grew over the 6-year period, we noticed a change in both patients' and referring physicians' attitudes toward subsequent pregnancies. Over the last 2 years, three women have chosen to undergo another pregnancy. In two of the three, the first treated fetus had presented with hydrops.

Comment

Our experience demonstrates that simple intravascular transfusion for the treatment of fetal hemolytic anemia can lead to an excellent perinatal outcome. It is safe in experienced hands and allows a term delivery in the absence of other obstetric indications.

Fetal anemia is the direct cause of many of the sequelae of hemolytic disease. The data suggest that the maintenance of the fetal hematocrit at near-normal levels throughout gestation accounted for the overall good neonatal outcome. The selection of a hematocrit that was actually <2.5th percentile for gestation as the threshold to initiate transfusion therapy was initially a pragmatic decision. Although we were reticent to begin therapy knowing that the fetus could tolerate a lower hematocrit well, we were unsure how rapidly a mild anemia might worsen. In hindsight, our selection appears to have been reasonable because several fetuses evaluated1 would have been transfused unnecessarily if the 2.5th percentile had been selected for the threshold, and hydrops developed in several high-risk fetuses with normal hematocrits over a 2-week interval.

The perinatal survival rate of 96% is similar to that in a slightly smaller series reported by Harman et al.5 (44 fetuses). However, this group performed their transfusions at closer intervals and delivered at earlier gestational ages. Although it was not our purpose to compare intravascular transfusion with intraperitoneal transfusion for the treatment of fetal hemolytic anemia, Harman et al. did. This is one of the few centers that has a large published experience with both intraabdominal and intravascular transfusion. They found an improved perinatal outcome with intravascular transfusion compared with intraperitoneal transfusion. Although another group reported a similar survival rate with a combination of amniotic fluid studies, intraperitoneal transfusion, and preterm delivery,6 this report seems an exception.5, 7-12 In addition, some fetuses

 $[\]dagger p = 0.06.$

p = 0.01.

transfused solely on the basis of amniotic fluid studies may not in fact need transfusion and thus may bias survival statistics in a favorable way. In a recent series of untreated isoimmunized pregnancies whose changes in optical density at 450 nm measurements were in zone III, Frigoletto et al. 13 noted that four of 11 fetuses (37%) had a hematocrit ≥30% at delivery and thus would not have qualified for transfusion by our criteria. Our experience14 with the relationship of the change in optical density at 450 nm to hematocrit is similar to that of Frigoletto et al.

In our study fetuses with hydrops had elevated umbilical venous pressures. We initially assumed this reflected obstructed venous return. However, the umbilical venous pressure characteristically fell into the normal range within 48 hours of the first transfusion. This argues against hepatomegaly and venous obstruction as a sole explanation for the increase. Rather it suggests that the increased umbilical venous pressure in hydrops is associated with myocardial dysfunction, perhaps as the result of tissue hypoxia associated with a critically low oxygen-carrying capacity. Transfusion would improve cardiac function by eliminating hypoxemia.

The only two losses were in severely hydropic fetuses. Each had a hematocrit <10% and a preexisting metabolic acidosis. In spite of the critical fetal condition, we do not feel these losses were inevitable. Each led to a modification in the transfusion protocol. The role of volume overload in the first loss is unclear and while fetal exchange transfusion would minimize the risk of volume overload it would not prevent the acidemia and would add greatly to the procedure time.

On the basis of the decline in fetal erythrocytes and reticulocytes, it would appear that fetal erythropoiesis can be suppressed within 6 weeks of initiating transfusion therapy. Alternatively, rapid hemolysis of erythroid progenitor cells on or before release from the marrow could account for this observation. However, the finding of erythroid hypoplasia in marrow aspirates of treated neonates argues against the latter possibility as a sole explanation.15 Further, we observed that neonatal hyperbilirubinemia was directly related to the reticulocyte count at birth and was more severe when only one antenatal transfusion had been performed. Although further study is needed, the 24% incidence of neonatal exchange transfusion in our series is less than that of neonates managed by either intraperitoneal transfusion or preterm delivery or both. 15, 16

Cordocentesis and intravascular transfusion are deceptively simple. In practice, they require an experienced team and a laboratory capable of performing a variety of tests on a small volume. Our series was drawn from a delivery base approaching 60,000 per year. It is not feasible from the standpoint of personnel and expense for every hospital to offer a similar service.

These are facilities that must be regionalized to maximize both safety and efficacy. The prior recommendation⁷ that a center perform ≥12 intraperitoneal transfusions per year or refer the patient to an experienced center is applicable to intravascular methodology.

In conclusion, treatment of fetal anemia by simple intrauterine intravascular transfusion is associated with a high survival rate, permits term delivery, and would appear to reduce immediate neonatal morbidity.

Lack of an association between late fetal death and antiphospholipid antibody measurements in the second trimester

James E. Haddow, MD, Neal S. Rote, PhD, Dorene Dostal-Johnson, MS, Glenn E. Palomaki, BS, Andrea J. Pulkkinen, MS, and George J. Knight, PhD Scarborough, Maine

To examine the relationship between elevated antiphospholipid antibody levels in the maternal circulation and late fetal death, we carried out a case-control study in which levels of anticardiolipin and antiphosphatidylserine antibodies were measured in banked second-trimester sera from 309 pregnancies ending in fetal death and from 618 viable control pregnancies. The sera were obtained from a population base of approximately 22,000 pregnancies enrolled for maternal α -fetoprotein screening between 15 and 20 weeks' gestation. The anticardiolipin immunoglobulin G level was markedly elevated (15.6 SD) in one serum sample associated with a fetal death. Otherwise, the anticardiolipin and antiphosphatidylserine measurements were similar in the two populations. Several other factors known to be associated with fetal death were also examined, and these all demonstrated the expected relationship. Antiphospholipid antibody measurements obtained at 15 weeks' gestation or later in the general pregnancy population are not helpful in identifying pregnancies at risk for fetal death. (AM J OBSTET GYNECOL 1991;165:1308-12.)

Key words: Antiphospholipid antibodies, second trimester, late fetal death, general pregnancy population

Elevated levels of antiphospholipid antibodies in blood (most prominently anticardiolipin and antiphosphatidylserine) are closely associated with lupus anticoagulant activity.1 The resultant hypercoagulable state can be assessed by measuring the partial thromboplastin time, which is lengthened as a result of the antiphospholipid antibody binding to negatively charged phospholipid molecules that participate in the prothrombin complex responsible for converting prothrombin to thrombin.24 Lupus anticoagulant activity was originally identified in patients with systemic lupus erythematosus, but now it is known to occur with other immunologic disorders and also as an isolated finding. In obstetrics, identifying lupus anticoagulant activity has become recognized as an important component in evaluating recurrent pregnancy loss1,4; it is estimated that 94% of pregnancies where the lupus anticoagulant is present will be nonviable, if untreated.⁵ In addition, two studies have reported elevated levels of anticardiolipin antibody in 13% and 40%, respectively, of patients being studied for unexplained recurrent pregnancy losses.6,7

Reprint requests: James E. Haddow, MD, Foundation for Blood Research, P.O. Box 190, Scarborough, ME 04070-1090. 6/1/30701 To date, only one published study has examined lupus anticoagulant and antiphospholipid antibody in a general obstetric population.⁸ In that study, two of 737 consecutively enrolled patients (0.27%) were found to have evidence of the lupus anticoagulant (both also had elevated anticardiolipin levels), and both pregnancies ended in spontaneous abortions. Elevated anticardiolipin levels without lupus anticoagulant activity were identified in an additional 14 pregnancies, and these were associated with a high rate of fetal deaths, preterm deliveries, and intrauterine growth retardation

This study used a case-control design to examine further the relation between antiphospholipid antibody and fetal death in a general pregnancy population, measuring both anticardiolipin and antiphosphatidylserine antibodies in banked sera.

Patients and methods

Patients. Sera from all pregnant women in Maine enrolling for routine maternal serum α -fetoprotein screening between August 1983 and November 1986 were coded and stored at -20° C. Subsequently, outcomes were obtained for 97% of these pregnancies. From this bank, 309 sera were identified from pregnancies ending in a nonviable outcome (cases), and each of these was matched for gestational age with sera from two viable pregnancies (controls) obtained within 2 months of the corresponding case serum sample. Although we are not aware of published data that relate

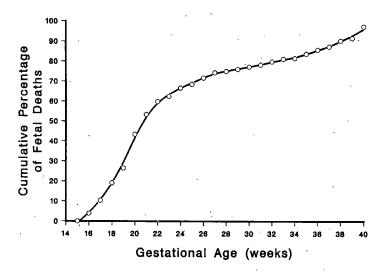

Fig. 1. Cumulative plot indicating time when fetal death was first identified in 309 cases.

to stability of antiphospholipid antibody in sera stored at -20° C, our own experience indicates that antiphospholipid antibody levels in serum samples with positive results remain stable for at least 6 years at that temperature. Fig. 1 is a cumulative plot of fetal deaths according to gestational age when first identified; two thirds of the deaths occurred by the twenty-fourth gestational week. All sera were obtained between 15 and 20 weeks' gestation, with a mean gestational age of 17.3 weeks. The samples were coded to protect confidentiality, blinded, organized into units of 33 case sera and 66 control sera, and submitted for analysis of antiphospholipid antibodies. Each unit of sera was thawed immediately before testing.

Antiphospholipid antibody enzyme-linked immunosorbent assay. Ninety-six-well microtiter plates (Immunolon I, Dynatech Laboratories, Alexandria, Va.) were prepared by diluting cardiolipin or phosphatidylserine (Sigma Chemical Co., St.Louis) in absolute ethanol to a final concentration of 45 µg/ml and adding 30 µl to each well. The solvent was allowed to evaporate overnight at room temperature in the dark. A total of 200 µl of assay buffer (10% fetal bovine sera in phosphate-buffered saline solution) was then added to each well; the plates were incubated at 25° C for 1 hour and then washed three times in phosphate-buffered saline solution with 1- to 2-minute incubations between washes. A total of 100 µl of a 1:100 dilution of each serum in assay buffer was added in duplicate, along with the calibrators and controls, and incubated for 1 hour at 25° C. The plates were then washed three times (as above), and 100 µl affinity-purified, Fc-specific, peroxidase-conjugated goat antihuman immunoglobulin G (IgG) (1:30,000 in assay buffer) or 100 µl affinitypurified, Fc5u-specific, peroxidase-conjugated goat antihuman immunoglobulin (IgM) (1:30,000 in assay buffer) (Jackson Immunoresearch, West Grove, Pa.)

was added and incubated at 25° C for 1 hour. The plates were then washed four times (as described), and color was developed by adding 100 µl tetramethylbenzidine and incubating for 4 minutes. Color development was stopped with the addition of 50 µl 0.06N hydrofluoric acid. The optical density was read at 650 nm on a Microplate Autoreader (BioTek, Winooski, Vt.). Spectrophotometric readings were adjusted by subtracting the readings observed on nonspecific binding plates (plates that did not receive phospholipid although they were processed in an identical fashion). The IgG assays were calibrated in antibody units with secondary reference standards prepared by serial dilution in assay buffer of a positive control containing 205 IgG phospholipid units (GPL).9 The IgM assays were calibrated similarly with a positive control containing 160 IgM phospholipid units (MPL).9

Data analysis. The population mean and standard deviation for each analyte was calculated after a log₁₀ transformation of antibody units. All individual results were then expressed in standard deviations above or below the mean. The 99th percentile of normal for each analyte was established by limiting the analysis to the 97% of control pregnancies with gestational age at delivery ≥37 weeks and a birth weight ≥2500 gm.

The Student t test for continuous and χ^2 test for discrete variables were the tests of significance for comparisons.

Results

Table I lists several comparative characteristics for the matched live births (controls) and fetal deaths (cases). Women in the two groups were of comparable age, and their serum samples were obtained at similar gestational ages. Years of education completed were lower among cases, and a greater proportion smoked

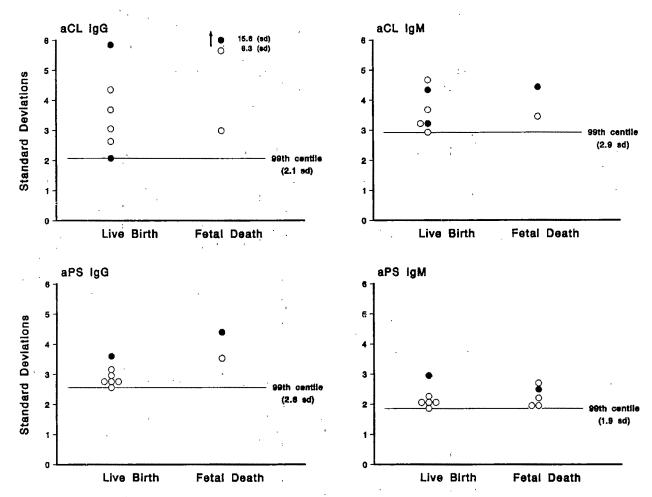

Fig. 2. Antiphospholipid antibody levels above 99th percentile of normal for 618 live births and 309 fetal deaths. Each circle represents serum antibody measurement from one individual, expressed as standard deviations above average of normal population. *Open circle*, Given individual's serum sample contains only one elevated antiphospholipid antibody concentration; *closed circle*, two antiphospholipid antibody concentrations are >99th percentile. Percents of antiphospholipid antibody values > 99th percentile in controls and cases for each antiphospholipid antibody type are as follows: anticardiolipin (*aCL*) IgG, 1% and 1%; anticardiolipin IgM, 1% and 0.6%; antiphosphatidylserine (*aPS*) IgG, 1% and 0.6%; antiphosphatidylserine IgM, 1% and 1.6%.

cigarettes, had suffered a previous spontaneous abortion, or experienced vaginal bleeding with the present pregnancy. Maternal serum α -fetoprotein values were also more often elevated in the cases than in the controls. All of these factors are widely recognized as being associated with fetal death.

Fig. 2 compares measurements of each of the four types of antiphospholipid antibody in the groups having live births or fetal deaths. For all four antiphospholipid antibody types, the proportions of measurements >99th percentile are similar in controls and cases, with only one outlying anticardiolipin IgG value (15.6 SD) associated with a fetal death.

Table II lists odds ratios for fetal death for each of the four antiphospholipid antibody types and compares them with four other factors recorded in the study population known to be associated with added risk for fetal death. An odds ratio >1.0 indicates that the risk for fetal death is higher when any given risk factor is present. Although the odds ratios for the four antiphospholipid antibody types vary from 0.57 to 1.67, none is significantly different from 1.0, as indicated by the 95% confidence intervals and p values. The limits specified for each of the four confidence intervals designate the range in which the true odds ratio lies. Therefore the upper limits of the confidence intervals indicate that it is unlikely that the true odds ratio is any higher than between 2.98 and 6.23, depending on the antiphospholipid antibody type measured. The odds ratios and confidence intervals are calculated with a 99th percentile cut-off, so that data from our study can be compared with those of an earlier published study. By contrast, the other four factors demonstrate significantly increased odds ratios consistent with the ex-

pected association, with the exception of cigarette smoking, which falls just short of achieving statistical significance.

Comment

The only other available antiphospholipid antibody related information from the general obstetric population comes from a study at the Yale-New Haven Hospital obstetric clinic, reported by Lockwood et al.8 In that cohort study 737 sequential eligible patients were enrolled at an average of 16 weeks' gestation, and partial thromboplastin times and anticardiolipin IgG and IgM measurements were performed. Sixteen of the pregnancies were associated with anticardiolipin levels >99th percentile, and six of these (37%) ended in intrauterine deaths, as opposed to 40 (6%) out of the remaining 718 pregnancies. The Yale study's findings yielded an odds ratio of 6.0 for fetal death in the presence of an anticardiolipin measurement >99th percentile (95% confidence interval, 1.9 to 18.5) and therefore differ substantially from our data. A partial explanation for the different findings may result from a proportion of the samples from the Yale study having been obtained earlier in gestation, as indicated by three of the six fetal losses occurring before 13 weeks' gestation. The population served by the Yale-New Haven Clinic is at generally higher risk than the population in this study, as evidenced by the rates of low birth weight, cigarette smoking, and human immunodeficiency virus. Whether and how the generally high-risk characteristics of that population might relate to the higher rate of positive anticardiolipin results remain to be explained.

Fetal death after submission of a serum sample for maternal serum α-fetoprotein screening in our population occurs at a rate of 14 per 1000; thus the 309 samples associated with fetal death come from a population base of approximately 22,000 pregnancies. Only one of the 309 sera from pregnancies associated with fetal death was found to have an anticardiolipin IgG value sufficiently elevated to suggest the antiphospholipid antibody syndrome. It is likely, however, that evidence of this syndrome will be found more frequently early in pregnancy than indicated by this study, because most of the antiphospholipid antibody-associated fetal losses are likely to occur before the second trimester. This study demonstrates that, in the general pregnancy population, serum antiphospholipid antibody measurements (including anticardiolipin IgG and IgM and antiphosphatidylserine IgG and IgM) obtained during the second trimester are similar for pregnancies ending in subsequent fetal death or in live birth and thus appear not to be clinically useful.

Severe ovarian hyperstimulation in a spontaneous singleton pregnancy

Gregory F. Rosen, MD, MS, and Mitchell W. Lew, MD

Irvine and Long Beach, California

Ovarian hyperstimulation syndrome in a spontaneous ovulatory cycle is exceedingly rare. We report a case of severe ovarian hyperstimulation associated with a spontaneous, otherwise normal singleton pregnancy. (Am J Obstet Gynecol 1991;165:1312-3.)

Key words: Ovarian hyperstimulation, CA 125, spontaneous ovulation

Ovarian hyperstimulation syndrome is a well-described clinical entity that usually represents the most serious complication associated with ovulation induction. Mild forms are infrequently associated with spontaneous ovulation and conception, primarily in the case of multiple gestations. A single case of severe ovarian hyperstimulation was reported in an anovulatory, non-pregnant patient who had trisomy 21 and was severely hypothyroid. We believe this to be the first report of a case of severe ovarian hyperstimulation associated with a spontaneously conceived singleton pregnancy in the absence of any medical problems and without evidence of trophoblastic disease.

Case report

pound weight gain over the previous 2 weeks without any associated change in dietary habits. She had a history of regular, 28-day menses for the last 3 years, but she had had an 11-week period of amenorrhea. Vital signs demonstrated orthostatic hypotension. The result of physical examination was remarkable in that the abdomen was severely distended and diffusely tender but with normal bowel sounds and no signs of peritoneal irritation. She denied the recent use of medication and had no signs of hyperandrogenism.

Laboratory testing revealed an elevated β -subunit human chorionic gonadotropin level (279,000 mIU/ml; normal, <200,000), elevated progesterone level (214 ng/ml; normal, <200), hemoconcentration (hemoglobin, 17.2 gm/dl; normal, 11.2 to 16), and a slight hyponatremia (131 mEq/ml; normal, 132 to 140). Platelet and white blood cell counts were normal, as were blood urea nitrogen level, creatinine level, and coagulation profile. Ultrasonographic examination revealed a viable intrauterine pregnancy whose size was consistent with dates, a normal placenta, massive ascites, and bilaterally enlarged cystic ovaries measuring 12×16 cm on the right and 15×17 cm on the left. She was admitted with a diagnosis of ascites, bilateral ovarian cysts, and possible partial mole.

Additional testing was performed. These included a

normal result of chest x-ray examination, normal-appearing liver-spleen scan, normal results of thyroid and liver function tests, and normal results of Doppler flow studies of the inferior vena cava and portal venous systems. The CA 125 level (Centocor, Malvern, Pa.) was elevated at 1284 U/ml (normal, 0 to 35). A diagnostic paracentesis produced fluid that was compatible with an exudative process. Its cultures were negative, and no malignant cells were found. She was maintained at bed rest with fluid and sodium restrictions, yet she continued to complain of abdominal pain and difficulty breathing. She gained 7 pounds over the next 2 days. Because this was an undesired pregnancy and given the patient's symptoms and findings, a therapeutic abortion and paracentesis were performed.

The uterine contents demonstrated normal fetal tissues. A tissue cell culture from fetal parts revealed a normal female karyotype, 46,XX, in all 20 cells counted. Multiple sections of the placenta were microscopically reviewed and no hydropic changes or trophoblastic proliferation was noted.

Diagnosis was changed to severe ovarian hyperstimulation, and she was maintained solely on a regimen of enough intravenous fluids to maintain a urinary output. Diuresis began 10 days after the therapeutic abortion. Three weeks after operation she had lost 30 pounds, and a repeat ultrasonographic examination demonstrated resolution of ascites. The ovaries did not return to normal size until 3 weeks later. β-Subunit human chorionic gonadotropin and CA 125 levels both returned to normal nonpregnant values within this time period. Luteinizing hormone and follicle-stimulating hormone levels determined 6 months after operation were 12 and 8 U/L, respectively, and the menstrual cycle had resumed its regular monthly interval.

Comment

The complex clinical picture of severe ovarian hyperstimulation is an infrequent but closely watched for finding associated with ovulation induction and controlled ovarian hyperstimulation. Mild forms of ovarian hyperstimulation have been reported previously in spontaneous conceptions but never a case as severe as this. Likewise, this young woman had no signs or symptoms of chronic anovulation or hyperandrogenism, i.e., polycystic ovarian syndrome.

Partial moles are very difficult to diagnose. The finding of a normal karyotype from a fetal part does not rule out the possibility that triploidy may exist elsewhere in the placenta or fetus but does decrease this

CA 125 levels can be elevated in women in many processes that can irritate the peritoneum. These include endometriosis, infections, and certain epithelial (nonmucinous) tumors of the ovary. CA 125 is associated with coelomic epithelium and amnion during embryonic development, so mildly elevated CA 125 levels are an expected finding in normal and abnormal pregnancy. Elevated levels also have been described during ovulation induction and with ovarian hyperstimulation,2 but the levels reported here are much higher. Theoretically, pregnancy and severe ovarian hyperstimulation have combined to cause these increased levels of CA 125 noted in this case.

Pseudoprognathism—An auxiliary ultrasonographic sign for transvaginal ultrasonographic diagnosis of cleft lip and palate in the early second trimester

M. Bronshtein, MD,^a N. Mashiah, MD,^a I. Blumenfeld, DMD,^b and Z. Blumenfeld, MD^a Haifa, Israel

Cleft lip and palate have been diagnosed antenatally only in the late midtrimester or at later gestational ages, when it is too late for pregnancy termination. The diagnosis of fetal cleft lip was made in three low-risk nulligravid women at 14 to 16 weeks of gestation by systematic screening with a 6.5 MHz transvaginal transducer and was confirmed by postabortal examination. (AM J OBSTET GYNECOL 1991;165:1314-6.)

Key words: Cleft lip, cleft palate, pseudoprognathism, transvaginal ultrasonography, early pregnatal diagnosis

Three cases of cleft lip and palate were diagnosed at 14 to 16 weeks of gestation by a 6.5 MHz transvaginal transducer.

Case reports

Case 1. A 35-year-old, nulligravid woman was referred for routine ultrasonographic scanning at 14 weeks' gestation. Her medical history was unremarkable.

Ultrasonographic examination of the fetal face revealed a cleft lip to the left of the midline, clearly evident on tangential section of the upper lip (Fig. 1, A). A sagittal left paramedian section demonstrated protrusion of the mandible, pseudoprognathism (Fig. 1, B). No other fetal anomalies were detected.

After informed consent was given by the patient, the pregnancy was terminated at 18 weeks' gestation by intraamniotic instillation of 40 mg prostaglandin $F_{2\alpha}$. Examination of the abortus confirmed the cleft lip and palate (Fig. 1, C) and a single umbilical artery. No other malformations were detected.

Case 2. A 35-year-old, gravida 3, para 3 woman was referred for ultrasonographic screening at 14 weeks of her fourth gestation. Her history was remarkable for mental retardation of her older child, of unknown cause. No consanguinity, exposure to possible teratogens, or family history of congenital anomalies was recorded. Chorionic villus sampling, performed at 9 weeks of the current gestation because of maternal age,

6/1/31192

recorded a normal, 46,XY karyotype. On transvaginal ultrasonography, pseudoprognathism—protrusion of the mandible—was detected only on one sagittal, paramedian section of the fetal head, compatible with a cleft lip of 1 to 2 mm width (Fig. 2, B). Pregnancy termination was performed at 15 weeks 5 days, by intraamniotic instillation of prostaglandin $F_{2\alpha}$. The cleft lip was confirmed on postabortal examination of the fetus (Fig. 2, D) without any other malformations.

Case 3. A 29-year-old, gravida 2, para 2 woman was referred for routine ultrasonographic screening at 16 weeks' gestation. Her medical history was unremarkable. On transvaginal ultrasonography holoprosencephaly and cleft midline were detected. A cleft lip was clearly visualized on both longitudinal and tangential sections of the upper lip. A sagittal median transvaginal ultrasonography section of the fetal head revealed a pseudoprognathism compatible with the cleft midline lesion. After informed consent, termination of pregnancy was performed at 16 weeks, confirming the diagnosed fetal malformations.

Comment

In spite of decades of intensive research regarding one of the most common anomalies, cleft lip and palate, full knowledge of its cause and pathogenesis remains elusive. There seems to be both a genetic and an environmental component in the etiology of these disorders. The incidence varies between 1 per 1000 live birth in whites to 1.7% in Japan. In 75% to 80% of cases the cleft lip is unilateral, more on the left side, and in two thirds of cases it is associated with cleft palate. The anomaly is more prevalent in male fetuses, 2:1. The genetic etiology of cleft lip seems to be an autosomal recessive major gene with reduced penetration. By the fourteenth week of gestation, the facial contour of the developing fetus is virtually complete. Therefore detection of this anomaly should be at-

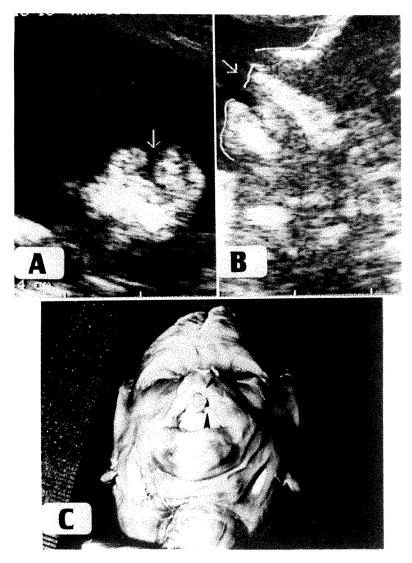

Fig. 1. A, Tangential transvaginal ultrasonographic section of upper lip demonstrating cleft lip (arrow) in case 1. B, Sagittal left paramedian section of same fetus demonstrating relative protrusion of mandible (pseudoprognathism) caused by cleft lip. C, Cleft lip (arrows) in aborted fetus (in case 1), confirming ultrasonographic diagnosis.

tempted as early as the fourteenth week, because cleft lip and palate may be associated with other fetal malformations in 7% to 13% of cases, some of them consisting of one of many syndromes.1

Prognathism, a relative protrusion of the mandible, is a rather common clinical occurrence. A total and an alveolar mandibular prognathism can be distinguished. In total mandibular prognathism the entire mental plate is obliquely inclined, but in alveolar prognathism only the alveolar process is inclined.

In contrast to the prognathism, which is usually caused by mandibular overgrowth, the pseudoprognathism that was detected by transvaginal ultrasonography in our three reported cases was seen in only one sagittal paramedian section (Figs. 1, B, and 2, B). The pseudoprognathism, or relative protrusion of the mandible as compared with the maxilla, could be detected only on the sagittal, paramedian section that passed through the cleft lip and palate. All the other sagittal sections of the same fetus did not show this protrusion because the maxilla and mandible were normally developed except in the area of the cleft lip and palate (Fig. 1, A). Therefore we suggest this ultrasonographic sign, clearly detected by us in the early second trimester in three cases of cleft lip, as an auxiliary ultrasonographic sign for the diagnosis of this fetal anomaly.

To the best of our knowledge, there was no description of fetal cleft lip or palate as early as 14 weeks' gestation.2 The early diagnosis allows for termination of pregnancy in cases where additional major malfor-

mations are diagnosed, after informed consent of the parents. In cases where parental choice was to continue the pregnancy, early detection at 14 to 16 weeks may allow for karyotype assessment by amniocentesis at 16 weeks. In families with previously affected children (by cleft lip and palate), visualization of normal facial contour may be reassuring for the anxious parents. This is also pertinent for previous fetal exposure to possible teratogens such as hydantoin or high doses of glucocorticosteroids.¹

We conclude that early second-trimester detection of cleft lip by transvaginal ultrasonography enables informed parental choice of continuing or terminating the affected pregnancy.

Extended longitudinal study of uterine activity among low-risk women

Denise M. Main, MD,^{a,b} Jeane A. Grisso, MD,^b Tiazu Wold, BA,^b Ellen Sim Snyder, MS,^b Iohn Holmes, MS,^b and Grace Chiu, PhD^b

Philadelphia, Pennsylvania

Eighty-nine black women without major medical risks for preterm labor participated in this longitudinal, prospective study for the evaluation of usual prelabor uterine activity and for the assessment of how gestational age, time of day, maternal weight, age, and parity affected contraction frequency. Participants wore an ambulatory tocodynamometer for 72 consecutive hours at three points in gestation during the second and early third trimesters while engaged in usual home and work activity. Data obtained from the 81 women with uncomplicated term pregnancies demonstrated a significant increase in contraction frequency with advancing gestational age between 22 and 33 weeks. After 26 weeks, significantly more uterine activity occurred at night. Perhaps because of detection difficulties, contraction frequency was inversely related to maternal weight in women weighing >112% ideal weight. Maternal age and parity did not affect contraction frequency. Contraction characteristics of eight women experiencing preterm labor or medically indicated preterm delivery are described. (AM J OBSTET GYNECOL 1991;165:1317-22.)

Key words: Normal uterine contractility, uterine contractility in pregnancy, tocodynamometry, diurnal rhythms

The recent introduction of ambulatory uterine activity monitoring has refocused obstetric interest on the importance of uterine contractions that occur throughout the second and third trimesters of pregnancy ("prelabor" contractions).1 Limited information is available about the normal range of prelabor uterine contractions, especially those occurring outside a hospital setting in women without major medical risks for preterm labor.2,3 An understanding of these phenomena would provide useful information for surveillance of normal pregnancies and for comparison with high-risk patients. In addition, tocodynamometry data from lowrisk women in home and work settings can be used to evaluate the effects of selected maternal factors (such as age, parity, and weight) on uterine contraction characteristics. To date, most studies have been done in women considered to be at high risk for preterm labor and have been directed toward achieving an early diagnosis of preterm labor. This is the first study to serially monitor medically low-risk women over several 24-hour periods outside the hospital.

Material and methods

Study population. In this prospective cohort study, 89 women were monitored for 72 hours at 4-week intervals at three points in gestation (weeks 22 to 25, 26 to 29, and 30 to 33). Participants were recruited by the study coordinator from the routine obstetric clinics of the hospital of the University of Pennsylvania between September 1986 and July 1987. All black women who presented for prenatal care before 24 weeks' gestation were approached and approximately one third agreed to participate in the study. The main reasons for refusal were concerns about equipment safety, inconvenience of study design, or lack of stable home environment. Women completing the study received \$10 per day monitored. Women with major medical risks for preterm labor (multiple gestation, history of preterm labor or delivery, and uterine malformation), were excluded, as were women with known substance abuse history, major psychiatric disease, and illiteracy. The study was approved by the Human Research Committee at the University of Pennsylvania.

The participants were all between the ages of 18 and 38 years (mean age, 24.1 ± 4.5 years) and 38% were nulliparous. These participant characteristics were similar to those of the overall clinic population.⁴ All participants explicitly denied cocaine or narcotic use, although urine and blood toxicology screens were not performed. (Substance abuse was not a widespread problem in our clinic population at the time.) For purposes of the study body weight was recorded as percentage of ideal weight for height and gestational age.⁵ Body weights varied widely: 16% were <90% of ideal weight, 32% were between 91% and 110%, 36% were

between 111% and 140%, and 16% weighed >140% of ideal weight. Eighty-one participants experienced uncomplicated term pregnancies, five had preterm labor, and three were delivered before 37 weeks' gestation because of medical complications (two with preterm premature rupture of the membranes, one with severe preeclampsia).

Determination of gestational age and preterm labor.

A clinically derived estimated delivery date was determined for each participant on the basis of last menstrual period and confirmed by first clinical estimate of size and first fetoscopic detection of heart tones. In addition, all patients had an ultrasonographic estimate of gestational age determined before 24 weeks of pregnancy. In 94% of cases, the ultrasonographic and clinical dates differed by <10 days, and in these cases the clinical dates were used. In five cases, when the dating disparity was greater, the ultrasonographic dates were used. To be diagnosed as having preterm labor, women needed to present with frequent uterine activity (minimum of four contractions in 20 minutes or eight contractions in 1 hour), as well as either cervical dilatation of ≥ 2 cm or effacement of $\geq 75\%$, or be observed to experience progressive cervical change. Patients not meeting these criteria did not receive tocolytics.

Uterine contraction monitoring. Participants were monitored during usual home and work activity. They were asked to wear a Termguard tocodynamometer for 72 hours, beginning on Monday evening of each study period. They were called by the study staff every 12 hours to transmit the uterine activity data by telephone. Monitoring was limited to weekdays to minimize variability that could be introduced by inclusion of different weekend activities. Compliance with the study was very good, with a mean of 61 hours of reliable contraction data per 72-hour study period (85%) obtained for interpretation and analysis.

The uterine monitoring strips were interpreted by one investigator, who was blinded to major study hypotheses, before the pregnancy outcome was known. Contractions were defined as smooth, symmetric deviations from baseline uterine tonus lasting at least 35 seconds and reaching a minimum of 2 mm in height. Intraobserver reliability was assessed by blinded rereading of a randomly selected 600 hours of uterine activity data. In 79% of the cases uterine contractions were identified identically, and in 95% of cases mean hourly contraction rates varied by one contraction per hour or less.

Data analysis. A descriptive analysis was undertaken to characterize uterine activity. Contraction frequency, intensity, and duration were recorded separately for each woman for each hour of each gestational age period monitored. Data for each individual were then combined and averaged to obtain mean hourly contraction rates and mean contraction intensity and duration for each of the three gestational age periods.

Values for all individuals with uncomplicated term gestations were combined to create summary estimates of contraction frequency, intensity, and duration for each gestational age period. Summary measures of contraction frequency, duration, and intensity were also assessed for specified time intervals within each gestational period, including each 24-hour period and two 12-hour periods (8 AM to 7:59 PM and 8 PM to 7:59 AM) for an averaged 24-hour day.

In the term, uncomplicated pregnancy group, a repeated-measures analysis of variance was used to examine whether contraction frequency (and likewise intensity and/or duration) significantly varied over the three gestational age periods, the 3 days within each study period, and the day versus night 12-hour intervals within each study period.6 The effects of three maternal variables (age, parity, and weight) on these contraction characteristics also were evaluated in the context of these models. Since the distribution of the contraction characteristics was skewed, natural logarithms were used to normalize the data. In addition, cosine analysis with a repeat period of 24 hours was applied to each individual's 72 hours of hourly contraction rates to determine if there were consistent diurnal rhythms.7

Multiple linear regression modeling also was used to assess the relationship between maternal weight and uterine contraction characteristics for each gestational age period. To determine whether there was a threshold to the apparent weight effect, piecewise regression analysis was performed to examine the relationship between weight and contraction frequency in different weight strata.8

Results

Uncomplicated pregnancies: Gestational age effects. In the group of 81 women with term, uncomplicated pregnancies, the average hourly contraction rate increased significantly with advancing gestational age (p = 0.0001 by repeated-measures analysis) (Table 1). When maternal weight, age, and parity were included in the model, the association between gestational age and contraction frequency remained significant (p = 0.01). Mean *intensity* of uterine contractions also increased significantly with increasing gestational age (p = 0.0001) (Table I). This effect remained significant even when maternal weight, parity, and age were included in the model (p = 0.03). In contrast, contraction duration did not change significantly with gestational age (Table I).

Uncomplicated pregnancies: Diurnal effects. On the basis of our review of the literature, we anticipated increased uterine contraction frequency in the evening and night hours as compared with the day hours. To test this hypothesis, we created two 12-hour data sets for each gestational age period, one consisting of all data recorded between 8 AM and 7:59 PM (day) and the

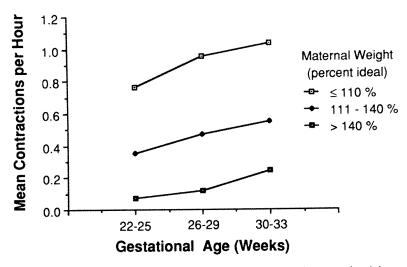

Fig. 1. Mean hourly contraction frequency by gestational age and maternal weight strata.

other contained all data recorded between 8 PM and 7:59 AM (evening and night). During the first gestational age period, the mean \pm SD hourly contraction rate for daytime hours was 0.39 ± 0.55 and the evening-night hourly rate was 0.57 ± 0.68 ; during the second period, 0.49 ± 0.64 and 0.76 ± 0.77 ; and during the third period, 0.62 ± 0.76 and 0.85 ± 0.84 , respectively. Repeated-measures analysis, controlling for maternal weight, was performed for each gestational age period. In each analysis a significant diurnal pattern was noted (p = 0.03 for the first, p = 0.001 for the second, and p = 0.02 for the third period). When maternal weight, age, parity, and sexual intercourse were included, the repeated-measures analysis remained significant only for the second (p = 0.002) and third (p = 0.003) periods.

To evaluate the regularity of the nocturnal increase in uterine contraction frequency, a cosine analysis was performed with the use of each participant's hourly contraction rate for each of the 72 hours monitored for each gestational age period studied. The purpose of this analysis was to determine if there was a 24-hour cyclicity to the individual uterine activity data. A correlation between the cosine curve and the individual's data points was required to reach a p value of <0.05 to be considered a significant fit. During the first gestational age period, 15.5% of the fits were significant. During the second gestational age period, 17.6% of the fits were significant. The percentage of significant fits was much higher in the third gestational age period at 39.7%.

Uncomplicated pregnancies: Effects of maternal weight, age, and parity. Maternal weight also had a clear relationship to uterine contraction frequency (p = 0.0001). As shown in Fig. 1, the mean hourly contraction rates for each of three maternal weight categories (≤110%, 111% to 140%, and >140% of ideal weight) demonstrate parallel increases with increasing

gestational age. Multiple linear regression modeling revealed an inverse relationship between maternal weight and contraction frequency that was similar for all three gestational age periods evaluated (p = 0.0001 for each gestational age). Because uterine contractions increase with gestational age and there was a range of 4 weeks for each gestational age period, we evaluated whether the increased uterine activity observed in thin women could be due to their enrollment at later gestational ages. Therefore we evaluated the relationship between maternal weight and gestational age at entry in the study and found that gestational age at enrollment was completely independent of maternal weight.

In a study reported by Nageotte et al.,9 women who were delivered after 42 weeks' gestation had lower contraction rates at some given point in gestation than women who were delivered at term. We next looked at maternal weight with respect to gestational age at delivery and found no relationship. Finally, using multivariate regression analysis, we evaluated the relation-

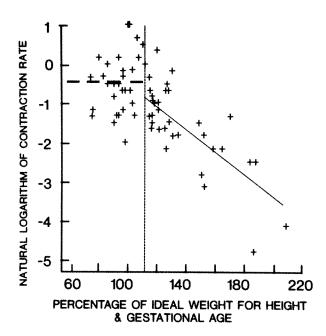

Fig. 2. Piecewise regression of contraction rate and percentage ideal maternal weight with threshold of 112% ideal weight. Regression line at <112% is nonsignificant (p=0.72) whereas that >112% is highly significant (p=0.0001). Data from second study period are presented.

ship of maternal weight on uterine contraction frequency, controlling for age and parity. The relationship between maternal weight and contraction rate remained highly significant for each gestational age period (p = 0.0001).

Because identification of a threshold above which uterine contraction rates are significantly related to maternal weight would be useful clinically, we evaluated our data in search of such a threshold. We used piecewise regression analysis, varying the weight cutoffs by percentage point between 110% and 125% of ideal maternal weight. We found that at <112% there was no significant relationship between maternal weight and contraction frequency in any of the three gestational age periods studied. When maternal weight was >112% ideal weight, there was a highly significant, inverse relationship between maternal weight and contraction frequency in all three gestational age periods studied (see Fig. 2). Each individual's percentage ideal body weight during the second study period was used throughout the analysis, although people varied minimally from one study period to the next with respect to this variable. All patients above the determined threshold remained so in all three study periods.

Wilcoxon-Mann-Whitney, Student *t*, and multivariate analyses were performed to determine whether maternal age or parity was related to contraction frequency, intensity, or duration. None of these maternal factors demonstrated any significant effects on uterine activity in our sample, nor did maternal weight have

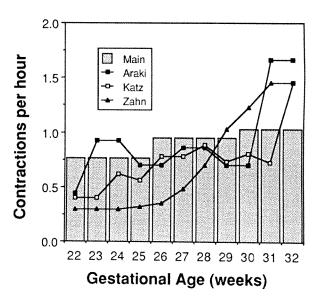

Fig. 3. Comparison of published data on contraction frequency by gestational age with current study results.

any independent relationship to contraction intensity or duration.

Complicated pregnancies. The primary purpose of this study is to provide descriptive data from low-risk women who were delivered at term. However, 8 of the 89 women in this study experienced either preterm labor (n = 5) or preterm birth without preterm labor (n = 3). Individual data for these women with complicated pregnancies including their percentages of ideal weight are shown in Table II. Although a number of results are above the mean for a given weight category and gestational age period, they do not appear to be out of the general range of values obtained from the 81 participants with uncomplicated pregnancies.

Comment

Contraction frequency. This study expands current knowledge about uterine contraction activity in the home and work setting among women with low-risk pregnancies. We have found only two other published studies dealing with uterine activity in ambulatory, lowrisk women.2.3 Zahn,2 using a telemetry device, monitored 26 nulliparous and 28 multiparous German women for 1 hour each day, between 25 weeks' gestation and delivery. Araki,3 using a portable device, provided cross-sectional data based on monitoring Japanese women at home for 30 minutes. The mean hourly contraction frequencies described by these investigators are quite similar to our more extensive data. In a study by Newman et al.10 of women at high risk for preterm labor, the uterine activity data for the 22 women with singleton pregnancies who did not have preterm labor are also similar to our data and those of Zahn and Araki (Fig. 3).

2		0.65	0.61	61.0

Note: Cases 1 to 5 were complicated by preterm labor and 6 to 8 by preterm premature rupture of the membranes or preeclampsia with abruptio placentae.

Other investigators have demonstrated an increased frequency of uterine contractions in women with preterm labor. 1, 3, 9, 10 This increase is often apparent for several weeks but becomes more pronounced during the 3 days preceding labor. Our study was designed to evaluate contraction characteristics in low-risk women who were delivered at term and not to assess the relationship between uterine contraction frequency and preterm labor. Thus the lack of a statistically significant difference in contraction rates in our study is not unexpected given the very small number of women with preterm labor and the wide spacing of monitoring periods (every 4 weeks).

Diurnal patterns of contraction frequency. Pregnant rhesus monkeys display a consistent circadian oscillation in contraction frequency in the latter part of pregnancy. The time of onset of peak contraction activity is around 7 PM with the onset of darkness.11 The activity reaches a maximum at 10 to 11 PM. These changes in contraction frequency are seen only in pregnancies with a live fetus. Increased uterine contractions at night are frequently observed in pregnant women with preterm labor.12 Analyses of large series of births also demonstrate higher rates of onset of spontaneous labor during the evening and night hours.13.14

However, other data about diurnal variations in prelabor contractions in human pregnancies are relatively limited. Zahn² studied 57 women between 32 and 41 weeks' gestation, presumably for one 24-hour period, while they were hospitalized for unspecified reasons. He noted a diurnal pattern similar to that seen in the rhesus monkey with a peak contraction frequency increase of >50% over the mean between 10:30 PM and 2 AM. However, this report provides no information on the variability among patients or the effect of gestational age on this pattern. Clearly, uterine activity in hospitalized patients who are monitored in the supine position may not accurately reflect contraction frequency in normally active pregnant women. Arakis monitored 22 Japanese women at different points in pregnancy, during both day and night hours. He found a fluctuating pattern that had no consistent relationship to gestational age. Contraction frequency increased at night in 38% of these women and decreased or remained unchanged at night in the other 62%.

Our findings of increased uterine activity at night in the last two study periods are not inconsistent with the limited information provided above. Although more women than expected by chance (particularly in the third gestational age period) had a 24-hour cyclicity of contraction frequency by cosine analysis, the majority of women did not. This is not surprising when one considers the many variables in a participant's daily schedule, including coitus and physical and emotional state.

Obesity. Although not described in the literature, it will not surprise many obstetricians that fewer contractions were detected in obese women. First, it is often difficult to palpate contractions and to obtain adequate monitoring data by means of standard labor and delivery equipment in obese women. Second, extremes in maternal weight are thought to influence pregnancy duration. In particular, very malnourished women are at increased risk for preterm deliveries.15 Examining the other weight extreme, one recent case-control study found a 16.4% rate of pregnancies lasting >42 weeks' gestation in women who weighed >250 pounds as compared with a 4.6% rate in controls who weighed <200 pounds. However, most studies that have examined the relationship between maternal weight (controlled for maternal height) and duration of gestation across a wide range of maternal weights have found, at best, very weak associations. In our current, relatively small sample of women delivered at ≥37 weeks' gestation, no association was present between ideal maternal body weight and pregnancy duration.

Inasmuch as there were no maternal weight-related differences with respect to pregnancy duration in this study, it is likely that the inverse relationship between maternal weight and contraction frequency in the heavier women reflects technical difficulty in monitoring increasingly obese women. The Termguard I device emits a warning signal until the tocodynamometer is applied against the abdomen with a minimum of 8 mm Hg baseline pressure. Although it is possible to increase the minimum baseline pressure to 12 mm Hg, this was not done in the current study. Such an approach might have enhanced the detection of contractions in the more obese participants. Further work to confirm the appropriate maternal weight threshold and evaluate the effect of belt tightening for obese patients would be useful. It is reassuring that we found no relationship between maternal weight and contraction frequency for women weighing ≤112% ideal weight for height and gestational age because most pregnant women remain in this normal to slightly obese range.

Parity. Like Zahn, we found no effect of parity on the frequency of prelabor contractions. This is of interest because during active labor, parity appears to influence the frequency of contractions. ¹⁸ When uterine contractions during labor are measured by internal pressure catheters, the parous uterus expended significantly less energy to reach complete dilation as compared with the nulliparous uterus.

In conclusion, our study presents the first extensive longitudinal observation of uterine contractility in pregnant women monitored in their own environments. Prelabor contractions increase significantly with increasing gestational age but remain at levels well below those considered abnormal. More uterine contractions were noted during the evening and night hours than during the day hours. Obese patients weighing >112% ideal weight have a significant inverse relationship between maternal weight and detected uterine activity. Finally, maternal age and parity do not appear

to influence uterine contractility before the onset of labor.

We thank Richard Wentworth, PhD, Susan Jenkins, and Peter Nathanielsz, MD, PhD, for performing the cosinor analysis presented in this paper. We also acknowledge the close cooperation and technical support provided by the Bell of Pennsylvania Company and by Tokos Medical Corporation, which were critical to the success of this study.

Videolaseroscopy for oophorectomy

Farr Nezhat, MD, Camran Nezhat, MD, and Sheryl L. Silfen, MD Atlanta, Georgia

Laparoscopic cophorectomy was performed on 94 ovaries in 76 patients. Indications included recurrent pain associated with endometriosis and adhesions in 17 patients (18 ovaries), ovarian endometriomas in 40 patients (40 ovaries), prophylactic cophorectomy (breast cancer) in one patient (2 ovaries), removal of the ovaries at the time of laparoscopic assisted vaginal hysterectomy in 15 patients (30 ovaries), and other indications in three patients (four ovaries). (AM J OBSTET GYNECOL 1991;165:1323-30.)

Key words: Operative laparoscopy, oophorectomy, videolaseroscopy, avoiding laparotomy, laparoscopy

Operative laparoscopy has been shown to be a safe, useful, and cost-effective alternative to laparotomy in cases of benign pelvic disease. 1-10 An increasingly wider variety of procedures are becoming possible, when performed by experienced operative laparoscopists.

Oophorectomy at laparoscopy with the use of endoloop suture has been previously reported.³ This report presents our experience with an alternative technique, videolaseroscopy (a combination of high-resolution video imaging and high-power carbon dioxide laser applied to operative laparoscopy) and electrocoagulation, to accomplish 94 consecutive oophorectomies.

Material and methods

All operations were performed by two surgeons (C.N. and F.N.), who have a combined experience of >5000 operative laparoscopies. All patients were seen in a private, largely referral clinical practice and operated on in an outpatient surgical suite of a large suburban hospital. From July 1987 to June 1990, laparoscopic oophorectomy, with videolaseroscopy techniques only, was performed on 94 ovaries in 76 patients ranging in age from 32 to 60. Indications were recurrent pain associated with endometriosis or pelvic adhesive disease, ovarian endometrioma (6 to 15 cm diameter), persistent ovarian cyst, prophylactic oophorectomy in breast cancer, and oophorectomy at the time of laparoscopically assisted vaginal hysterectomy; all patients undergoing laparoscopically assisted vaginal

hysterectomy had a history of endometriosis, adhesions, or leiomyomas, which precluded straightforward vaginal hysterectomy. Forty-eight patients had an intact uterus, whereas 28 had had hysterectomy. Tables I, II, and III summarize the clinical data regarding these 76 patients.

All patients with endometriosis or adhesions had previous medical or conservative surgical management that failed to relieve pain. The history was reviewed preoperatively, including previous operative reports, and pelvic examination and ultrasonographic examination were performed. Cases with unilocular ovarian cysts were initially managed by suppressive therapy with 50 µg estinyl estradiol-containing oral contraceptives or danazol. CA 125 levels were obtained for all patients beginning in 1988. Intraoperatively, the pelvis, upper abdomen, and diaphragmatic surfaces were inspected for signs of malignancy, and pelvic washings were obtained for cytologic testing. The cyst was then aspirated, and the fluid was examined grossly and sent for cytologic examination. The cyst wall was then opened and inspected for excrescences or irregular thickenings. Frozen-section histologic examination was done if, in

the judgment of the surgeon, the appearance was suspicious. All tissue obtained was submitted for permanent-section histologic examination.

All procedures were performed with the patient under general endotracheal anesthesia. Multiple abdominal punctures were used to introduce the laparoscope and suprapubic instruments. A miniature laparoscopemounted video camera with a high-resolution video monitor was used, allowing the operative field to be magnified and viewed by all operating room personnel and a more comfortable, upright position for the surgeon (Fig. 1). All procedures were video recorded to retain a permanent record on each patient. The carbon dioxide laser was introduced into the peritoneal cavity through the operating channel of the laparoscope with direct lens coupler and set at 30 to 80 W of power in superpulse mode for the purpose of cutting.5, 9-12 Bipolar forceps were introduced through a suprapubic portal and used for coagulation.

After the pelvis and abdomen were explored, oophorectomy was carried out in the following manner: Adhesions between the ovary and adjacent organs, pelvic walls, and broad ligament were lysed with a carbon dioxide laser. A Nezhat suction-irrigator probe (Cabot Medical, Langhorne, Pa.) and later a Nezhat-Dorsey probe (Karl Storz, Culver City, Calif.), introduced suprapubically, were used as a backstop and to provide constant suction, irrigation, and smoke evacuation. When the ovary was adherent to the lateral pelvic wall and in cases with previous hysterectomy, the technique of hydrodissection¹² was used to open the peritoneum, beginning at the pelvic brim, and to identify the course of the ureter and major blood vessels. With the same techniques, the descending colon and rectosigmoid colon were dissected from the site of the left infundibulopelvic ligament and ovary. Ovarian cysts were then aspirated, allowing easier handling of the deflated cyst and smaller ovary. Once the ovary was completely mobilized, it was held under tension with a grasping forceps, and the ovarian ligament was coagulated with bipolar cautery and transected with the laser at its junction to the uterus (Fig. 2). With 20 to 25 W, the cautery was applied briefly, desiccating and blanching but not overdesiccating the tissue, to reduce the blood flow to the pedicle to be transected. The mesovarium was then serially blanched, coagulated, and transected at 1 to 2 cm increments, working from medial to lateral, until the ovary was removed (Figs. 3 to 5). When the ipsilateral fallopian tube also was removed, the isthmic portion of the tube was severed and incised along with the ovarian ligament (Fig. 6); after identification of the ureter, the infundibulopelvic ligament was coagulated and transected at 1 to 2 cm increments, working from lateral to medial, until the adnexa were removed as described above (Figs. 7 and 8).

In most cases the ovary was removed from the peritoneal cavity through a 10 mm trocar sleeve placed in one of the suprapubic puncture sites. The ovary was grasped with a forceps, and then forceps and sleeve were removed together, delivering the ovarian tissue to the abdominal wall, where it was then grasped by a Kelly clamp and removed. In 25 patients (one with serous cystadenoma, nine with endometriomas associated with myomectomy, and 15 with laparoscopically assisted vaginal hysterectomy) the tissue was removed by posterior colpotomy.13 After removal of the ovary, thorough irrigation of the pelvic cavity was performed. The pedicles were then inspected under the water, both in the presence of a pneumoperitoneum and again after carbon dioxide evacuation, to ensure hemostasis after intraperitoneal pressure was reduced.

Results

Laparoscopic oophorectomy with the technique of videolaseroscopy was performed on 94 ovaries in 76 patients. The procedure was completed in each attempted case. Blood loss during oophorectomy was minimal. No major intraoperative or postoperative complications occurred, and no long-term complications have developed. No ovarian malignancies were encountered in this group of patients. Minor complications were limited to abdominal wall ecchymosis (two patients) and severe shoulder pain (nine patients).

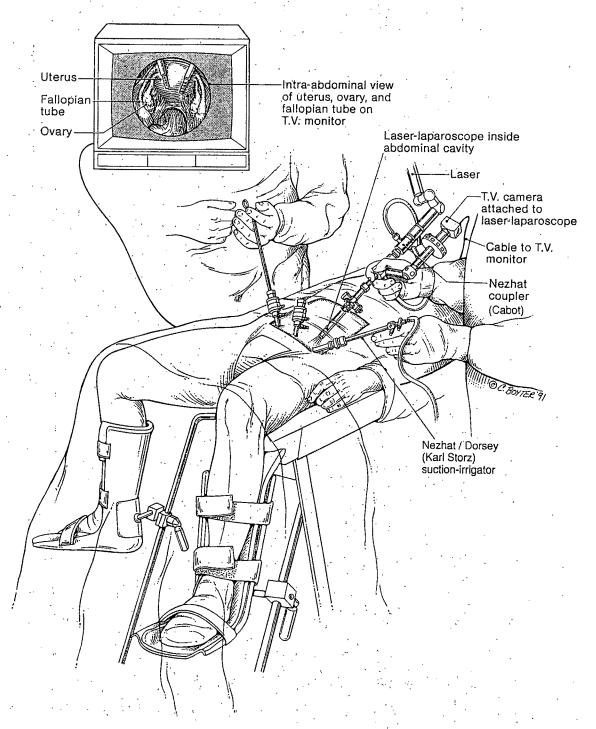

Fig. 1. Operating room setup.

The duration of oophorectomy was 22 to 55 minutes and was shortest in the patient requiring prophylactic oophorectomy, where no previous pelvic abnormality existed. Cases associated with myomectomy lasted 115 to 180 minutes, and laparoscopically assisted vaginal hysterectomy lasted 130 to 230 minutes.14, 15 While patients with laparoscopically assisted vaginal hysterectomy were discharged on the second or third postoperative day, all other patients were discharged within 24 hours, requiring an average hospital stay of 8.5 hours.

Comment

Oophorectomy is frequently necessary in patients experiencing chronic pelvic pain because of adhesions or endometriosis unresponsive to conservative medical or surgical therapy. Large endometriomas and benign ovarian cysts can destroy normal ovarian tissue, and oophorectomy may be selected in these cases, at the judgment of the surgeon. In the past, laparotomy was

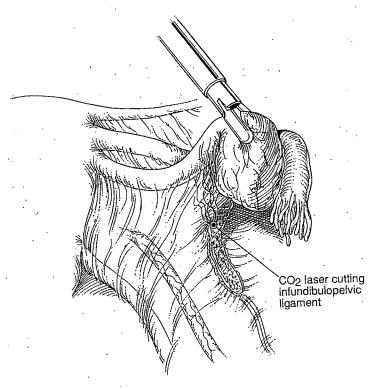

Fig. 4. Carbon dioxide laser used as a long knife through operative channel of laparoscope.

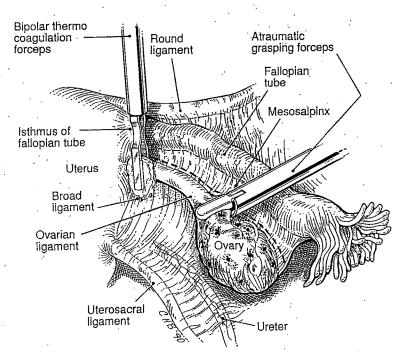

Fig. 5. Coagulation of ovarian ligament proximal to uterus.

the only surgical means to accomplish oophorectomy. Ovaries can now be removed at laparoscopy by experienced operative laparoscopists on an outpatient basis, resulting in shorter hospital stay, faster return to work, lower cost, and less adhesion formation. ^{16, 17}

Whereas laparoscopic oophorectomy has been reported with other techniques, videolaseroscopy offers some technical advantages to the operative laparoscopist. Perry and Upchurch, 18 using different instrumentations and techniques, performed oophorectomies in

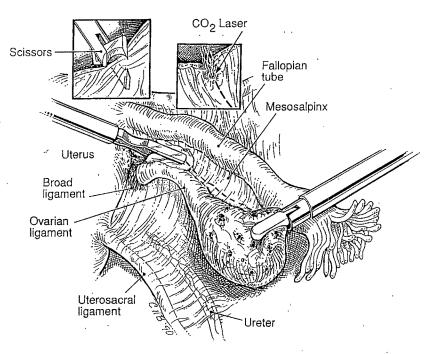

Fig. 6. Coagulation of ovarian ligament proximal to uterus.

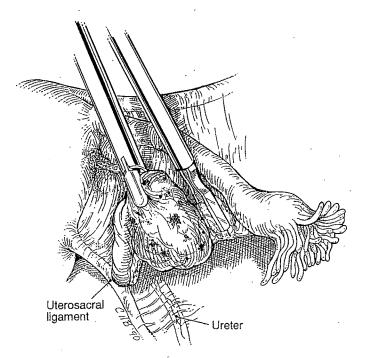

Fig. 7. Ovary has been freed from ureter and is under traction.

17 patients. One, with postoperative bleeding, required a laparotomy and transfusion. Six patients were excluded because of adhesions and an inability to visualize the ureter. In the majority of cases, pelvic adhesions must be lysed before the ovary can be mobilized, and ovarian anatomy is frequently distorted. Videolaseroscopy using the carbon dioxide laser and hydrodissec-

tion are an excellent combination for lysis of adhesions and entering the retroperitoneum¹⁹ to mobilize the ovary and remove it. In contrast, endoloop sutures cannot be applied in the presence of adhesions or distorted anatomy, and therefore additional instruments and techniques are required, thereby complicating the operating room setup. Furthermore, application of en-

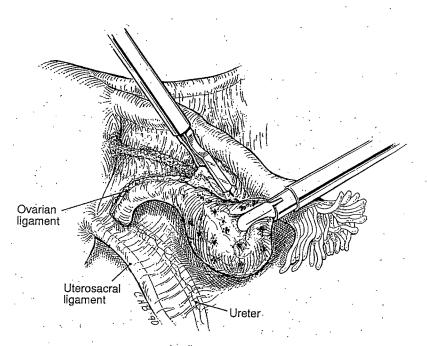

Fig. 8. Saving tube and removing ovary—position of ureter can be seen.

doloop sutures to large pedicles such as the mesovarium and infundibulopelvic ligament is awkward even in the absence of anatomic distortion. Once applied, the slip-knot can easily loosen under the tension of this large pedicle, increasing the risk of intraoperative hemorrhage and occasionally leaving a piece of ovary, causing ovarian remnant syndrome.

Complete desiccation of tissues with bipolar cautery, by means of generator amp meter, has been suggested before transection of pedicles.20 In our experience, however, desiccation to the point of blanching allows improved tissue healing without risk of hemorrhage. Overdesiccation (by allowing the amp meter to go to zero) creates friable tissue, which can actually predispose to intraoperative bleeding, and increased thermal damage that can theoretically produce postoperative adhesions. In addition, the pedals of the bipolar cautery device may stick to the tissue. Generators that provide a self-limiting bipolar desiccation mode minimize the chance for overdesiccation. Self-limiting bipolar cautery (Valley Lab Force series generators, Boulder, Colo.) provides controlled desiccation without charring the adjacent tissue. In this mode, the power peaks into a 100 Ω resistance instead of 300 to 500 Ω in typical generators. The power will then "roll off" at 1/resistance. This rapid but controlled "roll-off" provides the desired surgical effect without excess drying, blanching, or destruction of tissue.

Even after hemostasis has been achieved, in the presence of pneumoperitoneum, pedicles should be reinspected after evacuation of abdominal carbon dioxide. After intraabdominal pressure is lowered, ovarian pedicles have been noted to bleed again at termination of

the procedure. This maneuver offers one additional safeguard for complete hemostasis.²¹

Use of the carbon dioxide laser as the cutting instrument eliminates the tedious sequence of coagulating, removing the forceps, and introducing the scissors repetitively. In contrast, the laser remains available to the surgeon, always ready as a long knife, along the line of vision of the laparoscope, is operated by foot pedal instead of an additional hand, and functions to replace the scissors and, in many instances, the bipolar cautery as well. Finally, the posterior blade of the scissors becomes obscured by the tissue about to be cut, whereas the laser beam remains in view at all times, thereby eliminating any blind surgical manipulation.

In these 76 patients there were no major complications. Minor complications were associated with the laparoscopic procedure and not the oophorectomy. When there is no contraindication to laparoscopy, oophorectomy can be safely performed by an experienced operative laparoscopist at the time of diagnostic laparoscopy.

Laparoscopic oophorectomy appears to be a safe alternative to laparotomy, offering all the advantages of an outpatient surgical procedure. The techniques of videolaseroscopy simplify oophorectomy for the experienced operative laparoscopist.

Inappropriate secretion of antidiuretic hormone in Sheehan's syndrome: A rare cause of postpartum hyponatremia

Chaim Putterman, MD,^a Yaniv Almog, MD,^a Yoseph Caraco, MD,^a David J. Gross, MD,^b and Eldad Ben-Chetrit, MD^a

Jerusalem, Israel

A 27-year-old woman experienced hemorrhagic shock after delivery. One week later she was seen in an obtunded state of consciousness. The results of laboratory evaluation were consistent with the syndrome of inappropriate antidiuretic hormone secretion caused by hypopituitarism. Hydrocortisone rapidly corrected sodium levels. Syndrome of inappropriate secretion of antidiuretic hormone caused by Sheehan's syndrome should be considered in the differential diagnosis of postpartum hyponatremia. (Am J OBSTET GYNECOL 1991;165:1330-3.)

Key words: Antidiuretic hormone, hyponatremia, Sheehan's syndrome

Postpartum anterior pituitary necrosis (Sheehan's syndrome) infrequently causes hypopituitarism. Hyponatremia is a rare initial manifestation of postpartum pituitary insufficiency, particularly when it occurs within a few days of parturition. We report a case of

From the Departments of Internal Medicine A^a and Endocrinology and Metabolism, Hadassah University Hospital, Ein-Kerem. Received for publication March 5, 1991; revised April 24, 1991; accepted May 15, 1991.

Reprint requests: Chaim Putterman, MD, Department of Internal Medicine A, Hadassah University Hospital, Kiryat Hadassah, POB 12000, Jerusalem, Israel, 91120. 6/1/31190 A 27-year-old woman complained of headache and weakness. Seven days earlier she had been vaginally delivered of a healthy male infant. Immediately post partum she had an estimated 2 L uterine hemorrhage with shock. She was resuscitated with blood and colloids; hemorrhage was controlled with uterine massage, oxytocin, and ergotamine. One week after delivery she suddenly had paresthesias, slurred speech, headache, weakness, and somnolence. She also noted new diffi-

appropriate secretion of antidiuretic hormone.

Case report

A 27-year-old woman complained of headache and weakness. Seven days earlier she had been vaginally.

early Sheehan's syndrome initially seen as severe in-

culties with breast-feeding. Blood pressure was 120/80 mm Hg with no orthostatic change, and the heart rate was 80 beats/min. Eye grounds, visual fields, and the results of neurologic evaluation were normal. Axillary and pubic hair was present. The uterus was well contracted. The remainder of the results of the physical examination were within normal limits. The hematocrit was 28% and the hemoglobin was 9.9 gm/dl. The serum sodium level was 111 mmol/L, potassium 3.7 mmol/L, glucose 5.5 mmol/L, and urea 3.6 mmol/L. Urinalysis showed a sodium level of 116 mmol/L and a potassium level of 29 mmol/L. Baseline endocrine evaluation revealed markedly low levels of morning cortisol, 33.1 nmol/L (normal 110 to 520 nmol/L), and corticotropin < 1.1 pmol/L (normal 4 to 22 pmol/L). The triiodothyronine was 1.8 nmol/L (normal 1.2 to 3.4 nmol/L), thyroid-stimulating hormone 0.7 mU/L (normal 0.15 to 3.5 mU/L), prolactin 4.4 μ g/L (normal for a woman who is breast-feeding >50 μ g/L), growth hormone 1.2 $\mu g/L$ (normal < 5 $\mu g/L$), follicle-stimulating hormone 0.9 IU/L (normal 5 to 30 IU/L), and luteinizing hormone 21.4 IU/L (normal 5 to 20 IU/L). Therapy with intravenous isotonic saline solution and furosemide resulted in no significant change in blood sodium level. A 200 mg bolus of hydrocortisone was then administered intravenously, after which an additional 200 mg was continuously administered over 5 hours. Within hours, blood sodium levels increased to 123 mmol/L. Computed tomographic scan of the brain showed pituitary infarction with an increase in cerebrospinal fluid surrounding the gland (Fig. 1, A). When the patient received intravenous hydrocortisone therapy without fluid or salt restriction, normal sodium levels were attained and urine sodium level decreased to normal (Fig. 2). At 6 months' follow-up the patient was well and receiving maintenance therapy with hydrocortisone, levothyroxine, estrogen, and progesterone. Provocative pituitary testing confirmed panhypopituitarism. A follow-up computed tomographic scan of the brain demonstrated empty sella, with only remnants of the pituitary evident (Fig. 1, B). Complete results of the insulin-hypoglycemia, thyrotropin-releasing hormone and luteinizing hormone-releasing hormone tests are given in Fig. 3.

Comment

With the improvements in obstetric technique, the incidence of postpartum hemorrhage and subsequent pituitary insufficiency has appreciably decreased. Nevertheless, Sheehan's syndrome still causes hypopituitarism in women who bear children.

Chronic hyponatremia can infrequently appear in Sheehan's syndrome. However, hyponatremia as the initial manifestation of Sheehan's syndrome in the early postpartum period is extremely rare and has been reported only once. Sidorov and Mitnick¹ described an asymptomatic woman in whom a sodium level of 119 mmol/L was found 10 days after delivery. Evaluation confirmed panhypopituitarism, and the sodium level normalized with dexamethasone. However, this patient

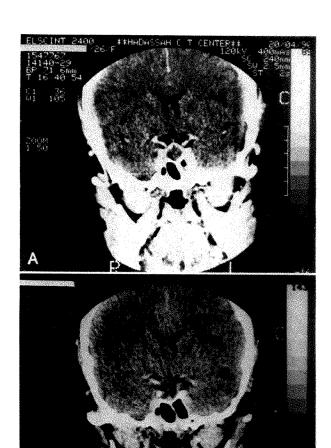

Fig. 1. A, Computed tomographic scan of brain demonstrating pituitary infarction with decrease in gland size. B, Repeat computed tomographic scan of brain shows almost total disappearance of pituitary tissue consistent with empty sella.

В

was completely asymptomatic, and the sodium level was not life-threatening.

Several hypotheses have been advanced to explain the pathophysiologic mechanism of hyponatremia in Sheehan's syndrome. Hypothyroidism can cause decreased free water clearance and hyponatremia. However, the relative hypothyroidism in our patient was not sufficient to explain the marked degree of hyponatremia. Glucocorticoid deficiency can impair free water excretion through modulation of collecting duct permeability independent of vasopressin. Aldosterone secretion is generally regarded to be independent of pituitary regulation by corticotropin, although decreased aldosterone secretion may contribute to hyponatremia in some patients.

Glucocorticoid deficiency can cause hypovolemia and hypotension, leading to baroreceptor-mediated appropriate release of vasopressin. There was controversy as to whether the glucocorticoid deficiency of hypopituitarism can also cause inappropriate secretion of antidiuretic hormone. Oelkers2 recently found inappro-

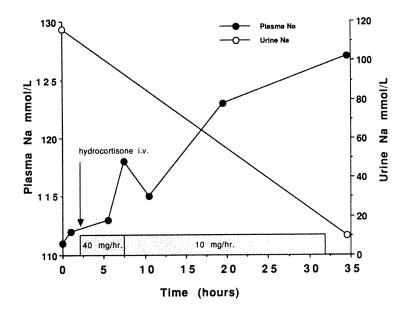

Fig. 2. Increase in blood sodium levels with concomitant decrease in urine sodium levels after hydrocortisone. *Arrow*, Start of hydrocortisone therapy (200 mg bolus); *shaded box*, duration of intravenous hydrocortisone therapy.

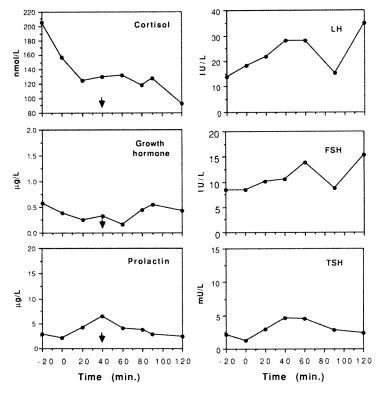

Fig. 3. Pituitary hormone response to combined pituitary function test. Thyrotropin-releasing hormone (400 μg) and gonadotropin-releasing hormone (100 μg) were administered at 0 minutes with 40 mU/kg/hr of insulin. *Arrows*, Time of nadir blood glucose level (2.3 mmol/L); *LH*, luteinizing hormone; *FSH*, follicle-stimulating hormone; *TSH*, thyroid-stimulating hormone.

priately high vasopressin levels relative to plasma osmolality in five women with chronic hypopituitarism and hyponatremia (two with Sheehan's syndrome). The relationship between antidiuretic hormone and osmo-

lality normalized with maintenance hydrocortisone therapy. Synthesis of vasopressin by the hypothalamus and its secretion by the posterior pituitary seems to be under inhibitory control by corticosteroids. Hypopi-

tuitarism is an important nonosmotic stimulus for antidiuretic hormone secretion and can cause severe inappropriate secretion of antidiuretic hormone.

In summary, we report a case of postpartum hypopituitarism that caused inappropriate secretion of antidiuretic hormone and hyponatremia. Replacement therapy with hydrocortisone increased sodium blood levels to normal. Even when appearing in the early postpartum period, severe hyponatremia can be the initial manifestation of Sheehan's syndrome.

Congenital heart block: Successful prophylactic treatment with intravenous gamma globulin and corticosteroid therapy

Risto Kaaja, MD, Heikki Julkunen, MD, Pirkko Ammälä, MD, Anna-Maija Teppo, MSc, and Pekka Kurki, MD^c

Helsinki, Finland

In mothers with anti-Ro-positive antibodies whose previous pregnancies have ended in deliveries of infants with congenital heart block, prophylactic therapeutic strategies are used to try to diminish the production and passage into fetal circulation of autoantibodies. Intravenous gamma globulin was given at 14 and 18 weeks' gestation and prednisone was given from 14 weeks' gestation to a woman with Sjögren's syndrome. The pregnancy ended with delivery of an infant without congenital heart block. (AM J OBSTET GYNECOL 1991;165:1333-4.)

Key words: Intravenous gamma globulin, congenital heart block, anti-Ro antibodies

Neonatal lupus syndrome and congenital heart block occur in infants whose mothers have antibodies to Ro (SS-A) and La (SS-B) autoantigens. The antibodies cross the placenta and may have a pathogenetic role in tissue damage in the fetus. Therefore therapeutic strategies such as plasmapheresis and corticosteroid therapy are used to diminish the autoantibody production and passage into the fetal circulation. The risk of congenital heart block is 1 in 20 pregnancies in which the mother has anti-Ro antibodies. If the mother has had an infant with congenital heart block, the risk in subsequent pregnancies is one in four. We report a high-risk pregnancy that was treated with intravenous gamma globulin and orally administered corticosteroids.

Case report

The patient was a 38-year-old woman with primary Sjögren's syndrome and hypothyroidism that began in 1978. Her first pregnancy was normal, and she was delivered of a healthy infant in 1974. During her second pregnancy 14 years later Sjögren's syndrome was inactive. At 22 weeks' gestation fetal bradycardia (60 beats/min) was observed and a diagnosis of congenital heart block was made with ultrasonography. Double immunodiffusion determined that anti-Ro-antibody titers were elevated (1:8), but no anti-La antibodies were found. She was delivered of an infant whose heart was structurally normal except for congenital heart block. A pacemaker was inserted. One year later during her third pregnancy the anti-Ro-antibody titer was 1:1, but no anti-La antibodies were found. Intravenous gamma globulin (Sandoglobulin, Sandoz, Bern, Switzerland) was given at 14 and 18 weeks' gestation with a dose of 1 gm/kg during 16 hours of infusion. Prednisone was given at 14 weeks' gestation with an initial dose of 40 mg/day and tapered within 4 weeks to 10 mg/day until delivery. After the second infusion of gamma globulin, anti-Ro antibodies were not detectable by double-immunodiffusion technique (Fig. 1). Enzyme immunoassay was also used to detect nonprecipitating anti-Ro

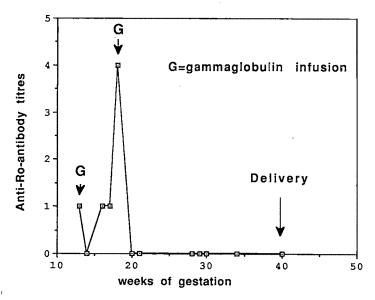

Fig. 1. Effect of intravenous gamma globulin on anti-Ro (SS-A) antibodies (1:1) measured with double-immunodiffusion technique.

antibodies. There was only a slight decrease in antibodies with solid-phase immunoassay. No signs of fetal bradycardia were observed, and a healthy child with normal heart function was born.

Comment

There are several mechanisms by which the combined corticosteroid and intravenous immunoglobulin therapy could be beneficial in an antibody-mediated disease. In addition to the simple antiinflammatory effect of corticosteroids and the dilution effect of intravenous immunoglobulin infusion, we can conjecture that there is a blockade of the transplacental pathway of antibodies.

Corticosteroids will also slowly diminish antibody productions. Jerne's theory of an idiotype-antiidiotype regulation of the immune system has gained strong experimental support. The antiidiotypes of normal human serum are able to interfere with autoantibodies present in a patient's sera. Such antiidiotypes are present in the intravenous immunoglobulin used in our case.

Thus it is possible that antiidiotypes are partly responsible for the decrease in the anti-Ro titer in the immunodiffusion test. This elimination may take place on the cellular (production) level or in the circulation (elimination). It is also possible that the antiidiotypes interfere in the immunodiffusion test used for the anti-Ro assay.

Interestingly, the therapy did not have a similar impact on the anti-Ro levels as measured with a solid-phase enzyme immunoassay. It is obvious that the immunodiffusion test and the solid-phase immunoassay detect different autoantibody populations. Most moth-

ers who have anti-Ro-positive antibodies give birth to normal children. Therefore it is possible that there is a pathogenetic subgroup of anti-Ro or other antibodies that are sensitive to immunomodulation by intravenous immunoglobulin.

The timing of therapeutic intervention is important in the prophylaxis of congenital heart block. There are no reports of successful outcome if the treatment has been started after fetal bradycardia is observed (usually >22 weeks' gestation). There are two reports in which a reduction of anti-Ro-antibody titers was achieved after steroid therapy and plasmapheresis and led to delivery of a healthy child. In these cases the treatment was given before 20 weeks' gestation.²

Our report of successful early prophylactic therapy is in agreement with these reports. Experimental prophylactic therapies should be restricted to high-risk pregnancies under research protocols with informed consent until controlled data are available. It is not clear that the good outcome of this case was related to the infusion of gamma globulin; it may be that the outcome was unrelated to the therapy. However, we think that intravenous immunoglobulin infusion is a good substitute for more laborious and hazardous techniques such as plasmapheresis. The immunoglobulin should be infused before the onset of bradycardia, which is an indicator of cardiac damage.

Amniotic fluid contains tissue factor, a potent initiator of coagulation

Charles J. Lockwood, MD, Ronald Bach, PhD, Arabinda Guha, PhD, Xiaodong Zhou, MD, Wayne A. Miller, MD, and Yale Nemerson, MD

New York, New York, and Lexington, Massachusetts

A primary clinical manifestation of amniotic fluid embolism is coagulopathy. Prior studies have identified a poorly characterized yet potent procoagulant property in amniotic fluid that increases with gestational age. One possible source of procoagulant activity is tissue factor, a primary biologic initiator of coagulation. We used sensitive immunoassays and functional assays to identify substantial quantities of tissue factor antigen and tissue factor—specific procoagulant activity in amniotic fluid, which increased with gestational age. Moreover, tissue factor accounted for virtually all of the coagulant potential of amniotic fluid. Amniotic tissue factor appeared intact and membrane bound and, when reconstituted into synthetic microvesicles of optimal phospholipid content, displayed nearly full activity. Calcium chelation and sonication experiments suggested that the presence of inhibitors and the physical configuration of membrane-bound tissue factor in amniotic fluid might explain the modest reduction in tissue factor procoagulant activity relative to total antigen levels observed in vivo. We postulate that the substantial quantities of functionally active tissue factor in amniotic fluid account for the coagulation changes accompanying amniotic fluid embolism and could indirectly contribute to the characteristic hemodynamic derangements of amniotic fluid embolism. (AM J OBSTET GYNECOL 1991;165:1335-41.)

Key words: Amniotic fluid embolism, tissue factor, lipoprotein-associated coagulation inhibitor

Amniotic fluid embolism is a rare but calamitous obstetric event, with maternal mortality rates exceeding 80%. The most common hemodynamic abnormality identified in affected patients is an elevation in pulmonary capillary wedge pressure accompanied by evidence of left ventricular failure. A potentially lethal clinical coagulopathy is present in 40% of cases; however, subtler coagulation abnormalities may be present in the remainder of patients.

While the mechanisms for the maternal hemodynamic derangements in amniotic fluid embolism remain obscure, the etiology of the concomitant coagulopathy is equally enigmatic. Amniotic fluid has been shown to have a direct factor X-activating property.² This property increases toward term, paralleling the

boplastin-like property is present when amniotic fluid is added to normal plasma, an effect that also increases with gestational age. These findings suggest that amniotic fluid may contain tissue factor or other components of the extrinsic pathway of coagulation.

development of fetal pulmonary maturity.3 A throm-

Coagulation has traditionally been studied in a glass tube under static conditions. However, such investigations focused on circulating intrinsic pathway components and not cell-mediated coagulation. The latter is initiated by tissue factor, and it is this extrinsic pathway that maintains hemostasis in vivo.⁵ Tissue factor has an apparent molecular weight of 40,000 to 46,000.⁶ It is a true cofactor and does not require proteolysis for activation but must be membrane bound for activity.^{5,7}

Disruption of vascular integrity is required for tissue factor—mediated hemostasis, because tissue factor is sequestered in the subendothelium and adventitia and does not circulate in plasma. Once exposed to blood, tissue factor binds to factor VII, which, although a zymogen, is partially active. Because cleavage of factor VII results in a 120-fold increase in this activity, the designation factor VII(a) is used to indicate that both zymogen and enzyme are active. The affinity of tissue factor for factor VIIa is increased in the presence of acidic membrane phospholipids. The complex of tissue factor—factor VII(a) can activate either factor X or

IX and thus trigger clotting. Once tissue factor is exposed to blood, its potent procoagulant effects are eventually inhibited by lipoprotein-associated coagulation inhibitor, a 38,000 molecular weight protein that forms a calcium-dependent quaternary complex with tissue factor, factor VIIa, and factor Xa. 10-12

The purpose of this investigation was to determine whether tissue factor and other extrinsic pathway components are present in the amniotic fluid and therefore contribute to the pathogenesis of amniotic fluid embolism.

Material and methods

After we received informed consent from the patients, amniotic fluid specimens were obtained from amniocenteses for fetal pulmonary maturity (37 to 39 weeks' gestation) and karyotype (16 to 18 weeks) studies. Sample volumes were 5 and 2 ml, respectively. All specimens with meconium or gross or microscopic evidence of red blood cell contamination were discarded. Samples obtained from pregnancies complicated by maternal infection, abruptio placentae, multiple gestations, and fetal anomalies were excluded. All amniotic fluid specimens were maintained at -80° C until used. For the purpose of analysis specimens within 2 weeks of gestation were subsequently pooled in volumes of 20 to 30 ml. These pooled specimens (n = 7 for each trimester) were then aliquoted into a whole amniotic fluid sample, a cell-free, low-speed (1000g for 15 minutes at 4° C) centrifugation supernatant containing membrane microvesicles, and a corresponding lowspeed, cell-enriched pellet.

Tissue factor enzyme-linked immunosorbent assay. Membrane-bound tissue factor was solubilized by the addition of 0.1% Triton X-100 and measured with a sensitive enzyme-linked immunosorbent assay (ELISA).13 This ELISA used a well-characterized murine monoclonal antibody against human tissue factor in the solid phase¹⁴ and a polyclonal anti-tissue factor antibody to amplify the murine monoclonal antibodybound tissue factor signal. The polyclonal antibody was raised as described13 and affinity purified by protein A-Sepharose and a human tissue factor-affi-Gel column (Bio-Rad, Hercules, Calif.). Goat antirabbit immunoglobulin G conjugated to horseradish peroxidase (Boehringer-Mannheim, Indianapolis) and the substrate orthophenyldiamine were used to visualize the complex. After acid quenching, the optical density at 490 nm was read with an automated microplate reader (Molecular Devices, Menlo Park, Calif.). Concentrations of amniotic fluid tissue factor were derived in triplicate from a standard curve with the SOFTMAX computer program (Molecular Devices). The linear

range of the standard curve run with each assay was 0 to 155 μ g/ml (r > 0.99). Intraassay variations were <5%.

Tissue factor functional assay. A modification 15 of the two-stage tissue factor clotting assay of Nemerson¹⁶ was used to measure concentrations of functionally active human tissue factor in amniotic fluid specimens. Reagents included human factor VIIa and factor X prepared by barium citrate adsorption followed by ionexchange chromatography and molecular size separation with an ultragel AcA-44 column (Bio-Rad), as described. 17, 18 The linear range of the assay's standard curve was 5 to 200 pg/ml. Amniotic factors VIIa and Xa did not contribute to spurious estimates of tissue factor concentration because repetition of each assay in the absence of added factor VIIa or X greatly prolonged the clotting time. To further confirm that tissue factor was primarily responsible for amniotic fluidinduced clotting, parallel samples of amniotic fluid were preabsorbed with molar excess anti-tissue factor murine monoclonal antibody before assay.

Immunoblot and tissue factor-membrane reconstitution studies. To determine if amniotic fluid tissue factor was degraded or synthesized in a truncated, potentially inactive form, solubilized tissue factor derived from whole amniotic fluid was extracted by immunoaffinity purification, and its electrophoretic size was evaluated by immunoblot analysis, in comparison with immunopurified human brain tissue factor, as described by Bach et al.19 In addition, a known amount of immunopurified amniotic fluid tissue factor was suspended in 0.1% Triton in 0.1 mol/L sodium chloride and 0.05 mol/L Tris buffer, pH 7.5, precipitated in cold acetone (0° C), and resuspended in 375 mmol/L of the nonionic dialyzable detergent octyl-β-D-glucopyanoside (Sigma Chemical Co., St. Louis) with phosphatidylserine and phosphatidylcholine. Subsequent dialysis of octyl-\beta-p-glucopyanoside resulted in formation of reconstituted microvesicles with a tissue factor/phospholipid ratio of 1:100,000 and a phosphatidylserine/phosphatidylcholine ratio of 30:70, optimal for tissue factor procoagulant activity.7, 9 These reconstituted microvesicles were then assayed for both tissue factor antigen and activity.

Sedimentation analysis of amniotic tissue factor. To ascertain why amniotic fluid tissue factor procoagulant activity was reduced relative to total tissue factor antigen levels, amniotic fluid cell-free, low-speed supernatant fractions from the second and third trimesters were subjected to either (1) calcium chelation with 20 mmol/L ethylenediaminetetraacetic acid for 30 minutes at 20° C to disrupt putative calcium-dependent tissue factor—inhibitor complexes, (2) probe sonication

for 30 seconds three times at 0° C to disrupt possible multilayered membrane macroaggregates that could impede tissue factor-factor VII(a) binding, (3) both of these, or (4) neither of these. Ultracentrifugation at 143,000 g for 16 hours at 4° C was then used to separate sedimented membrane-bound tissue factor from free tissue factor, coagulation factors, and inhibitors. This high-speed pellet and supernatant were then assayed for tissue factor antigen and activity.

Assays for lipoprotein-associated coagulation inhibitor. To assess specific sources of tissue factor inhibition in amniotic fluid, pooled whole amniotic fluid and cell-free, low-speed supernatant specimens from the second and third trimesters were assayed for lipoprotein-associated coagulation inhibitor concentrations by ELISA and a functional tissue factor inhibition assay as described.20, 21

Relipidation experiments. To determine if variations in amniotic fluid membrane phospholipid constituents contributed to the observed disparities between tissue factor antigen concentrations and activity, the cell-free, low-speed supernatant and high-speed pellet from both second- and third-trimester amniotic fluid specimens were subjected to either (1) membrane disruption with 375 mmol/L octyl-β-D-glucopyanoside alone or (2) 375 mmol/L octyl-β-D-glucopyanoside plus phosphatidylserine and phosphatidylcholine to produce tissue factor/phosphatidylserine/phosphatidylcholine microvesicles of optimal coagulation potential.19 After incubation at 37° C for 2 hours, samples were exhaustively dialyzed in 0.05 mol/L Tris buffer, pH 7.5, and assayed for tissue factor antigen and activity

Coagulation assays for factors IIa, Xa, and VII(a). Amniotic fluid factor IIa concentrations were assessed by amidolytic assay with the thrombin-specific substrate H-D-hexahydrotyrosyl-L-alanyl-L-arginine-pnitroanilide22 according to the manufacturer's specifications (Sp-TH, American Diagnostica, Inc., New York). Absorbance readings, corrected for the intrinsic absorbance of amniotic fluid at 405 nm, were obtained after acid quenching, and amniotic fluid factor Ha levels were derived from a factor IIa (Sigma) standard curve. Amniotic fluid factor Xa concentrations were assessed by a similar amidolytic assay with the use of a specific factor Xa chromogenic substrate, MeO-CO-D-Gly-Arg-nitroanilide (Sp-Xa, American Diagnostica), and purified factor Xa18 as a standard. The percentage of amniotic fluid factor X existing in the zymogen versus active form was assessed by preincubation of samples with a direct, calcium-independent activator of factor X, Russell's viper venom (Sigma).

Amniotic factor VII(a) levels were measured by a

modified prothrombin time with the use of factor VII(a)-deficient plasma, according to the manufacturer's specifications (Baxter Healthcare Corp., Miami). Immunopurified human factor VIIa, prepared as described,17 was used as a standard, and human recombinant tissue factor (Genetech, South San Francisco) was used as a thromboplastin source at 50 ng/ml. The specificity of this assay for VII(a) was confirmed by prior incubation of parallel amniotic fluid specimens with selective covalent inhibitors of factor Xa and IIa, Phe-Pro-Arg-chloromethylketone (Calbiochem, San Diego) (1 µmol/L) and dansyl-Glu-Gly-Arg-chloromethylketone (Calbiochem) (10 µmol/L) (Guha A, Nemerson Y. Unpublished observations) respectively. The proportion of amniotic fluid factor VII existing in the zymogen versus active state was assessed by prior incubation of amniotic fluid with the specific covalent inhibitor of factor VIIa, Phe-Phe-Arg-chloromethylketone (Calbiochem) (10 μmol/L),23 followed by exhaustive dialysis of excess inhibitor.

Protein assay. Protein concentrations of amniotic fluid specimens were measured by a modified Bradford assay (Bio-Rad, Richmond, Calif.).

Results

Tissue factor ELISA and functional assay. Concentrations of tissue factor per milligram of amniotic fluid protein in whole amniotic fluid, its derivative cell-free supernatant, and cell-enriched pellet are presented in Table I. Term amniotic fluid specimens demonstrated higher tissue factor concentrations whether measured by ELISA or functional assay compared with those of second-trimester specimens. Whereas gestational age differences in tissue factor antigen levels were a consequence of the higher amniotic fluid protein concentrations in the second trimester compared with term specimens (8.8 \pm 2.4 vs 4.8 \pm 1.6 mg/ml, p = 0.002), functional tissue factor concentrations measured in nanograms per milliliter of fluid were significantly increased at term compared with those of the second trimester $(0.89 \pm 0.19 \text{ vs } 0.49 \pm 0.24 \text{ ng/ml}, p =$ 0.01). Moreover, the ratio of tissue factor concentrations measured by functional assay versus ELISA were consistently greater in term compared with secondtrimester specimens (Table II). Preadsorption of amniotic fluid with excess anti-tissue factor murine monoclonal antibody virtually eliminated amniotic fluidinduced clotting in the functional assay, suggesting that tissue factor was responsible for nearly all the procoagulant activity of amniotic fluid.

samples consistently demonstrated two discrete, intact forms of tissue factor, as previously described ¹⁵ (Fig. 1). The higher-molecular-weight (46,000) form of tissue factor predominated in amniotic fluid, whereas human brain tissue factor displayed its major band at 40,000. Reconstitution of immunopurified amniotic fluid tissue factor into synthetic microvesicles of optimal phospholipid content restored nearly all the potential tissue factor activity (function/antigen = 0.91). Thus amniotic fluid tissue factor exists in an intact and potentially fully active form.

Sedimentation analysis of amniotic tissue factor. All amniotic fluid tissue factor appears to be membrane bound, because the ultracentrifuged supernatants contained negligible quantities of tissue factor antigen and activity. Both calcium chelation and probe sonication resulted in substantial increases in tissue factor activity relative to a given amount of antigen in the high-speed pellets. Table III presents the findings of a representative experiment, which suggests that both the physical configuration of tissue factor within a membrane complex and calcium-dependent tissue factor inhibitors in amniotic fluid may contribute to the observed relative reduction in tissue factor activity.

Assays for lipoprotein-associated coagulation inhibitor. Concentrations of lipoprotein-associated coagulation inhibitor antigen were 26.0 and 28.6 ng/ml in second-trimester whole amniotic fluid and cell-free, low-speed supernatant samples, respectively. Comparable values from a term specimen were 19.8 and 23.9 ng/ml, respectively. However, lipoprotein-associated coagulation inhibitor functional activity could not be identified in any specimen in spite of its nearly fourfold molar excess when compared with tissue factor in these specimens.

Relipidation experiments. No significant increase in tissue factor functional activity resulted from phospholipid reconstitution of native amniotic fluid microvesicular membranes at a phosphatidylserine/phosphatidylcholine ratio optimal for tissue factor functional activity. Thus amniotic fluid membrane phospholipid constituents do not appear to contribute to decreased activity within and between trimesters.

Coagulation assays for factors IIa, Xa, and VII(a). Low levels of factors Xa, VII(a), and IIa were identified in amniotic fluid (Table IV). Amniotic factor IIa levels appeared to be increased at term. Preincubation of amniotic fluid with Russell's viper venom had no effect on

107k

Fig. 1. Western blot of immunopurified tissue factor from pooled second-trimester amniotic fluid specimens, performed as described by Bach et al. 19 From left to right: lane A, Human brain tissue factor (50 ng); lane B, molecular weight standards (BRL Life Technologies, Inc., Gaithersburg, Md.); lane C; tissue factor (11 ng) from fraction 2 of affinity column elution. Note that tissue factor derived from both human brain and amniotic fluid appears intact. However, major electrophoretic band for tissue factor derived from human brain has apparent molecular weight of 40,000 (small arrow), whereas major band of amniotic fluid-derived tissue factor has molecular weight of 46,000 (large arrow). Identical immunoblot findings were obtained for amniotic fluid tissue factor derived from term specimens. (46, 46,000-Molecular-weight standard; 107k, 107,000-molecular-weight standard.)

factor Xa measurements, confirming that the active form of factor Xa predominates in amniotic fluid. Preincubation with a factor VIIa-specific inhibitor indicated that the zymogen, factor VII, is the predominant moiety in second-trimester whole amniotic fluid, whereas the active moiety, factor VIIa, predominates at term.

Comment

This study has systematically evaluated tissue factor and other extrinsic pathway components and potential inhibitors in amniotic fluid. We have found substantial tissue factor procoagulant activity in amniotic fluid, although it is relatively reduced in comparison with the amount of antigen. We have been able to account for

prior observations that whole amniotic fluid-induced coagulation activity increases with gestational age by identifying higher amniotic fluid tissue factor procoagulant activity at term compared with the second trimester. We have also noted that amniotic fluid tissue factor exists in an intact, membrane-bound state without evidence of degraded or truncated forms. The predominance of the higher-molecular-weight form for tissue factor derived from amniotic fluid compared with brain-derived tissue factor may reflect different glycosylation patterns. However, such differences are unlikely to effect coagulation potential, because glycosylation does not alter tissue factor procoagulant activity.7 Similarly, the phospholipid content of membranes does not appear to account for the decrease in procoagulant activity relative to total antigen levels.

In contrast, the physical conformation of membrane-bound tissue factor in amniotic fluid may reduce functional activity. Membrane macroaggregates could prevent access by bound tissue factor to free factor VII(a). Calcium-dependent inhibitors also may reduce activity. An immunoassay for a plasma tissue factor inhibitor, lipoprotein-associated coagulation inhibitor, demonstrated high antigen levels; however, this lipoprotein-associated coagulation inhibitor appeared inactive. Perhaps amniotic fluid lipoprotein-associated coagulation inhibitor is degraded or subject to a unique inhibitor. Alternatively, trophoblast-derived, calcium-dependent tissue factor inhibitors, such as placental anticoagulant protein,²⁴ may be present in amniotic fluid.

The source of tissue factor in amniotic fluid remains unknown. Cultured WISH amniotic cells synthesize tis-

sue factor.⁷ Sloughed fetal skin is a likely source, because the outer epidermis is rich in tissue factor.²⁵ Respiratory tract, gastrointestinal, and genitourinary mucosal epithelia also contain tissue factor and could contribute to the amniotic fluid tissue factor pool.

The presence of substantial tissue factor—specific procoagulant activity in amniotic fluid and the inhibition of amniotic fluid procoagulant activity by anti—tissue-factor antibodies suggest that tissue factor accounts for the bulk of the potent procoagulant properties of amniotic fluid. Moreover the markedly low concentrations of factors IIa, VIIa, and Xa measured in amniotic fluid (Table IV) stand in contrast to the mean maternal plasma concentrations of their zymogens at term (2300, 34.2, and 254 nmol/L, respectively). This suggests that amniotic fluid—derived activated coagulation factors probably contribute minimally to the coagulation abnormalities accompanying amniotic fluid embolism.

We speculate that the deportation of sufficient quantities of whole amniotic fluid—derived tissue factor into the pulmonary microvasculature will engender a number of disparate effects. Local factor IIa (thrombin) generation could cause vasoconstriction and microvascular thromboses.²⁸ Thrombin also can stimulate vascular endothelin secretion in cultured bovine endothelial cells.²⁹ Endothelin has been shown to increase left atrial pressure and depress cardiac output in a canine model,³⁰ effects also observed in humans with amniotic fluid embolism. Moreover, endothelin receptors have been detected in human coronary arteries.³¹ Therefore both the hemodynamic and coagulation effects of am-

niotic fluid embolism could theoretically result from deportation of active tissue factor into the pulmonary microcirculation.

We thank Dr. George Broze for his analysis of amniotic fluid lipoprotein-associated coagulation inhibitor concentrations and Dr. Roberto Romero for his guidance and support.

Laser vaporization of grade 3 vaginal intraepithelial neoplasia

Mitchel S. Hoffman, MD, William S. Roberts, MD, James P. LaPolla, MD, James V. Fiorica, MD, and Denis Cavanagh, MD

Tampa, Florida

Between March 1, 1984, and May 23, 1990, 26 patients underwent laser vaporization for grade 3 vaginal intraepithelial neoplasia. Twenty of these patients had prior hysterectomy, 12 of them because of cervical neoplasia. Ten patients had undergone prior treatment for vaginal intraepithelial neoplasia. Eleven (42%) developed recurrence of vaginal neoplasia with a mean time to recurrence of 22 weeks. Three of the 11 patients had invasive cancer at the time of recurrence. One patient had invasive cancer on biopsy at the time of laser vaporization and subsequently underwent radiation therapy. The remaining 14 patients remain alive with no evidence of recurrent disease at a mean follow-up interval of 117 weeks. In our hands, laser vaporization did not appear to be efficacious treatment for grade 3 vaginal intraepithelial neoplasia, especially when diagnosed in the region of a vaginal cuff scar. (AM J OBSTET GYNECOL 1991;165:1342-4.)

Key words: Laser, vaginal neoplasia

Vaginal intraepithelial neoplasia accounts for approximately 0.4% of lower genital tract intraepithelial neoplasia.1 Identifiable risk factors for this condition include cervical intraepithelial neoplasia,2 previous pelvic radiotherapy,3 human papillomavirus infection,4 and immunosuppression.2-5 The invasive potential of vaginal intraepithelial neoplasia appears to be similar to that of cervical intraepithelial neoplasia.2,6 The process most commonly occurs in the upper third of the vagina and is frequently multifocal.7-11 Vaginal intraepithelial neoplasia is usually diagnosed during investigation of an abnormal Papanicolaou smear; it is not grossly visible and does not usually produce symptoms. The diagnosis is established by colposcopy with directed biopsy. A wide variety of treatments have been used, most commonly consisting of local excision, partial or total vaginectomy, radiotherapy, laser vaporization, or topical 5-fluorouracil.12 Each of these treatment methods have different advantages and disadvantages, and none has proved superior efficacy over the others. This is a report of our experience with the use of laser vaporization for grade 3 vaginal intraepithelial neoplasia.

Material and methods

The charts of all patients with grade 3 vaginal intraepithelial neoplasia managed by our division between Jan. 1, 1984, and June 1, 1990, were reviewed retro-

. . . .

It was not possible to accurately define how patients were selected for laser vaporization over some other form of treatment. All patients underwent colposcopy of the entire lower genital tract. A directed biopsy of visualized lesions was performed, with separate biopsies performed of areas with varying appearance. Large and small swabs were used to aid visualization. Skin hooks were not used. In general, our division's criteria for laser vaporization of grade 3 vaginal intraepithelial neoplasia include a completely visualized lesion that has been sampled as indicated with no suspicion for invasive cancer and that cannot be managed by a small local excision. All laser procedures were performed by an obstetrics and gynecology resident under the direct supervision of one of the five attending physicians. All procedures were performed in the operating room with the patient under general or regional anesthesia. All procedures were performed with colposcopic guidance and by a Sharpland 1060 carbon dioxide laser at a power density of 500 to 1000 W/cm². Lesions were vaporized to a depth of 1 to 2 mm, including at least a 1 cm margin of surrounding normal-appearing mucosa. All cases were managed on an outpatient basis unless concomitant procedures required an additional stay. Patients were examined at 2 weeks, 8 weeks, and then every 2 to 3 months after surgery for the first 2 years and every 6 months thereafter, unless there was recurrence of disease. All new lesions diagnosed in the follow-up period were, for purposes of this report, considered recurrences.

spectively. A total of 41 patients had been treated, 26

either primarily or secondarily with laser vaporization.

Results

The mean age of the 26 study patients was 57 years (range, 19 to 80 years). Twenty (77%) patients had

NA. Not available.

*All three patients with invasive cancer at the time of recurrence had undergone radical hysterectomy because of invasive squamous cell carcinoma of the cervix.

undergone hysterectomy. Eight of these were because of benign disease and 12 were because of squamous neoplasia. Four patients had undergone pelvic radiotherapy because of malignancy. Three of these were squamous cervical cancer and one was endometrial cancer. Ten patients (38%) had undergone therapy for vaginal intraepithelial neoplasia or vaginal human papillomavirus. These treatments included one laser vaporization in two patients, two laser vaporizations in one patient, upper vaginectomy in one patient, cautery in one patient, cryotherapy in one patient, 5fluorouracil cream in two patients, and multiple treatments in two patients.

The vaginal intraepithelial neoplasia was located in the upper third of the vagina in 15 of the patients, in the upper half of the vagina in three, in the anterior midvagina in one, and at multifocal sites in the remaining seven. Seven of the patients underwent additional procedures at the time of laser vaporization. Three of these were because of cervical intraepithelial neoplasia, three because of vulvar intraepithelial neoplasia, and one because of both cervical and vulvar intraepithelial neoplasia. The mean operative time was 42 minutes, with a range of 15 to 60 minutes. The estimated blood loss was reported as scant to <5 ml in all patients. There were no reported intraoperative complications and two reported postoperative complications. One patient had difficulty with diabetic control in the immediate postoperative period and another who was severely immunosuppressed had problems with healing, with essentially minimal healing at the time of a small recurrence 8 weeks after operation.

Recurrent vaginal neoplasia developed in 11 (42%) of the patients (Table I). The mean time to recurrence was 22 weeks, with a range of 8 to 78 weeks. Two of the recurrences were diagnosed at 64 and 78 weeks and may have represented new lesions. All 11 patients had undergone hysterectomy. In 10 of the 11 patients both initial and recurrent disease were at the apex of the vagina around the vaginal cuff scar. Four of the 11 patients had significant risk factors for recurrence, including two severely immunosuppressed patients, one patient who had undergone pelvic radiotherapy, and one patient who had experienced multiple treatment failures for vaginal intraepithelial neoplasia. Three of the 11 patients had invasive cancer at the time of the recurrence; all had been treated for invasive carcinoma of the cervix and all underwent radiotherapy. One patient eventually died as a result of the cancer. In two of the three patients it was thought that the invasive cancer had developed from epithelium that was buried within the vaginal cuff scar; these cases have been reported previously.18 One patient had superficially invasive cancer on a biopsy specimen obtained just before laser vaporization; she received radiotherapy after operation and was excluded from follow-up analysis. Invasive cancer at the time of recurrence was diagnosed in all three patients by pathologic examination of an upper vaginectomy specimen. Four other patients with recurrence underwent upper vaginectomy; one was treated with 5-fluorouracil cream, and three received multiple types of treatments. Fourteen patients remain alive with no evidence of recurrent disease at a mean follow-up interval of 117 weeks (range, 46 to 240 weeks). Follow-up information regarding anatomy and sexual function was inadequate for reporting.

Comment

A wide variety of methods have been used to treat vaginal intraepithelial neoplasia, including partial to total vaginal excision, radiotherapy, laser vaporization, and topical 5-fluorouracil.2,7,9,12-24 Good results generally have been obtained with these methods, although the results have been more variable with laser vaporization.12, 14-17, 19-24 Laser vaporization for vaginal intraepithelial neoplasia has been variously reported to have a 50% to 100% success rate. Some of these studies have included patients who have undergone two laser vaporizations. Partial or total vaginectomy has been considered by many to be the treatment of choice, mainly because it excises the abnormal tissue and provides a specimen for complete histologic review. 18, 18, 19 However, several advantages of laser vaporization and 5-fluorouracil have been cited, including reduced operative morbidity, less operative time, and improved subsequent sexual function. 14-18, 20-23 Laser vaporization or 5-fluorouracil also may be preferable in cases of previous irradiation, because of the excessive morbidity associated with vaginectomy. Patients who have a tendency toward recurrence of vaginal intraepithelial neoplasia also may benefit from these treatments and the reduced amount of shortening and scarring that may result from multiple applications of other forms of treatment (i.e., excision).

Before treatment with laser vaporization is considered, an accurate appraisal of the extent and severity of the disease must be made. This is facilitated by using colposcopy, Lugol's iodine, palpation, and multiple biopsies. Laser vaporization should not be performed unless the full extent of the abnormal vaginal epithelium can be visualized, there is no suspicion of an invasive process, and there is no gross scarring or distortion of the posthysterectomy vaginal cuff. The last point has been made by several authors, including a prior study from this institution, and a few isolated case reports of vaginal intraepithelial neoplasia and invasive cancer arising from such vaginal cuffs have been published. 13-21 The results of this study underline this problem.

Vaginal intraepithelial neoplasia in the upper vagina of women who have undergone hysterectomy probably should be excised along with the vaginal cuff scar. This seems especially important for patients in whom hysterectomy was performed because of cervical cancer or intraepithelial neoplasia, in whom the vaginal cuff is prominent or distorted, or who have had treatment failure with laser vaporization or topical 5-fluorouracil. On the basis of the results of this study, we believe that laser vaporization should not be used for the treatment of grade 3 vaginal intraepithelial neoplasia diagnosed in the region of a vaginal cuff scar. Laser vaporization certainly could be combined with an excision of the cuff scar area.

On reducing the frequency of severe abruptio placentae

Jack A. Pritchard, MD, F. Gary Cunningham, MD, Signe A. Pritchard, RN, and Ruble A. Mason, RMT

Dallas, Texas

At Parkland Memorial Hospital the frequency of abruptio placentae so severe as to kill the fetus has decreased from 1 in 420 deliveries during 1956 through 1969 to 1 in 830 during 1974 through 1989. Major factors in this reduction were elimination of very high parity and a marked increase in the percentage of Latin American women, in whom the risk was 1 in 1473 deliveries compared with 1 in 595 for black women and 1 in 876 for white women. Abdominal trauma was encountered rarely, as was fetoplacental-to-maternal hemorrhage sufficient to impair fetal perfusion seriously. Abnormal development of Müllerian ducts and uterine myomas were encountered rarely. Neither red blood cell macrocytosis characteristic of folate deficiency nor iron deficiency could be implicated in the genesis of severe abruptio placentae. Abruptio placentae recurred in 12% of subsequent pregnancies and proved fatal to the fetus in 7%, unchanged from our earlier experience. (AM J OBSTET GYNECOL 1991;165:1345-51.)

Key terms: Severe abruptio placentae, recurring abruptio placentae, high parity and abruptio placentae, race and abruptio placentae

Severe abruptio placentae, defined as premature placental separation of such magnitude as to kill the fetus, persists as an important cause of serious maternal morbidity and even mortality and a prominent cause of fetal death. Previously published studies from Parkland Hospital on 201 cases managed during 1956 through 1969 identified high parity, hypertension, and recurrent abruptio placentae to be much more common in pregnancies so complicated when compared with the general obstetric population.1 It was commented then that, "Hopefully, identification of factors of etiologic importance in the genesis of severe placental abruption will lead to a reduction in the frequency of this serious lesion." Indeed, as described in this report, the frequency of abruptio placentae more recently at Parkland Hospital was decreased by one half. Even so, abruptio placentae still accounted for 14% of all stillbirths.

In this report the answers to two questions especially have been sought: what accounted for the favorable reduction overall in the frequency of severe abruptio placentae so severe as to kill the fetus? and what might be done to reduce it further?

Material and methods

Texas Southwestern Medical Center at Dallas.

The term abruptio placentae has been applied to lesions ranging from focal, marginal placental sepa-

From the Department of Obstetrics and Gynecology, the University of

Received for publication July 25, 1990; revised February 27, 1991;

accepted April 8, 1991.

rations of minimal dimensions and causing little or no impairment of fetal well-being to detachments so extensive that placental function is inadequate for fetal survival. In the first circumstance aggressive intervention is unlikely to influence outcome unless the management itself adversely affects mother, fetus, or both. Moroever, it is not always possible, even in retrospect, to establish precisely either the extent or the duration of abruptio placentae simply by examining the delivered placenta. However, one well-defined category of major clinical importance is identifiable, namely, placental separation with loss of placental function so great that the fetus dies in utero. We have so defined severe abruptio placentae.

All Parkland Memorial Hospital inpatient, outpatient, emergency department, and family planning clinic records, and, when appropriate, records from other hospital and private physicians have been reviewed for the 207 cases of severe abruptio placentae cared for from 1974 through 1989. Most all of the laboratory studies were performed in the Obstetric Hematologic Research Laboratory using standard methods.

Results

The frequency of abruptio placentae so severe as to kill the fetus decreased from one in 420 deliveries during 1956 through 1969 to one in 830 during 1974 through 1989. The roles, if any, of the following factors in bringing about this reduction are considered.

High parity. In the 1956 through 1969 study, the risk of severe abruptio placentae was greatest among women of very high parity.1 Indeed, the frequency of severe abruptio placentae among women whose pre-

Latin American versus black and white, p = 0.00002.

delivery parity was ≥ 7 was 1 in 120, or seven times that for women whose parity was 1. In the previous study 37 of the 201 cases, or 18%, involved women with a parity of ≥ 7 compared with only two instances, or 1%, more recently, reflecting the dramatic decrease in the frequency of high parity that has been achieved for the general obstetric population at Parkland Hospital.

If the risk of severe abruptio placentae for each parity had remained the same as in the earlier period, the marked reduction in the frequency of high parity alone would have resulted in a decrease in the frequency from 1 to 420 to 1 in 576 deliveries, or 37%.

Some investigators have concluded that high parity is not a risk factor for severe abruptio placentae, but they were analyzing typically an obstetric population in which high parity was rare and, even though numeric differences were identified, these were not considered to be significant.²

Race. The frequency of severe abruptio placentae more recently was quite different for black, white, and Latin American women. While the mean frequency for all races was 1 in 830, it varied from 1 in 594 for black women and 1 in 876 in white women to only 1 in 1473 among Latin American women. These differences are highly significant (Table I). Age and parity among the three groups differed only slightly: Mean predelivery parities for black, white, and Latin American women were 1.12, 1.02, and 2.0, respectively, and mean ages were 21.5, 22.2, and 24.6 years respectively. Therefore the addition of a sizable number of Latin American women to the general obstetric population would serve to decrease the overall frequency of abruptio placentae so severe as to kill the fetus, and, indeed just that has occurred during more recent years at Parkland Hospital, as shown in Fig. 1.

In our 1956 through 1969 study, evaluation of the impact, if any, of race was not attempted because most of the women (83%) with severe abruptio placentae were black, but so were 76% of the general obstetric population, at that time. During the same period only 7% of women delivered at Parkland Hospital were Latin American, compared with 32% during 1974 through 1989. In retrospect, the 7% of Latin Americans

in the earlier study accounted for only 2.6% of the cases of severe abruptio placentae, in keeping with the finding that severe cases are much less common among Latin American than black women.

Racial differences in the predisposition to severe abruptio placentae have not been considered in most publications. The review by Naeye et al.3 of 53,518 pregnancies from 12 hospitals between 1959 and 1966 is an exception. Their analyses of cases of abruptio placentae and perinatal death provided by the Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disorders and Stroke led them to conclude that race had no significant influence on perinatal deaths caused by abruptio placentae. These investigators did not specify the races considered, but presumably they were predominantly white and black. In our recent experiences severe abruptio placentae was less common among whites than blacks, but the level of significance (p = 0.02) was not great, whereas for Latin Americans compared with black plus white women the difference was highly significant (p = 0.00002). Our study involved 171,780 deliveries, 54,326 of which were in Latin American women.

The intriguing, recently reported findings of Kleinman,⁴ that neonatal infant mortality among women of Mexican origin was less than one half that for black women, would suggest, at least, that pregnancy complications that compromise fetal well-being are likely to be less frequent or less intense among Latin American women when compared with black women.⁴

Prevalence of sickle cell trait. The frequency of hemoglobin S was determined among the 115 black women who more recently had severe abruptio placentae. There were no instances of sickle hemoglobinopathy, but sickle cell trait was identified in 5, or 4.2%. During these study periods, erythrocytes from 47,562 black women who attended prenatal and family planning clinics were screened for hemoglobin S; the result was positive in 8.1%.

Maternal sickle cell trait was not a factor in the genesis of severe abruptio placentae, nor did it intensify morbidity.

Maternal hypertension. Hypertension was defined as blood pressure repeated >140/90 mm Hg for >6 hours. If hypertension was identified remote from pregnancy it was classified as chronic. Blood pressure recordings remote from pregnancy were available in 97% of cases.

The frequency of hypertension from all causes was similar in both studies, averaging 52% in the more recent study and 47% earlier compared with 9.6% and 11%, respectively, in the general obstetric population. Acute hypertension was recently more common (33% vs 22% earlier); however, 44% of the general obstetric population delivered more recently were nulliparous and therefore at increased risk of pregnancy-induced hypertension, compared with 25% who were nulliparous in the earlier study. Among women with severe abruptio placentae more recently, the frequency of hypertension was 36% among white women, 49% in Latin Americans, and 59% in black women, compared with 9.8%, 10.8%, and 12%, respectively, in the general obstetric population who were delivered during the same period.

Whereas these observations confirm previous reports of a markedly increased frequency of hypertension in cases of abruptio placentae,1,2,5 they do not provide an explanation for the remarkably lower frequency of severe abruptio placentae among Latin American women compared with black women. The difference does not appear to be attributable to a much lower prevalence of hypertension and therefore a reduced predisposition to abruptio placentae in Latin Americans compared with the black general obstetric population because the frequency of hypertension in the two obstetric populations differed only slightly.

Recurring abruptio placentae. Eighty-two of the women in the current study are known to have conceived again 133 times; 20 of the subsequent pregnancies (15%) terminated in abortion, including two tubal pregnancies.

Fourteen (12%) of pregnancies in which birth weight was ≥500 gm were complicated again by abruptio placentae that was fatal to 8 (7%) of the fetuses. One mother (Case 6, Table II) died of postpartum complications that included severe hypertension, renal failure and respiratory distress, whereas in the earlier study all mothers survived. Thus fetal outcome was no better than in the period 1956 through 1969, during which 11% of the 139 subsequent pregnancies terminated with another abruptio placentae; in 7% the placental separation again proved fatal to the fetus, and maternal outcome was worse.

To try to identify, at least in retrospect, how these deaths from subsequent abruptio placentae might have been prevented, the 14 repeat instances were carefully reviewed. Summaries are provided in Table II. The

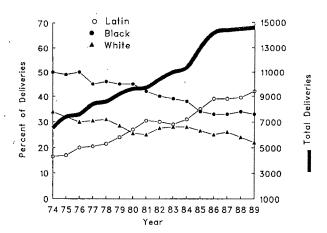

Fig. 1. Racial distribution of obstetric population at Parkland Memorial Hospital, 1974 through 1989.

opportunity to evaluate mother and fetus and intervene quickly while the fetus was still alive was important in the favorable outcome in 5 of the 6 cases of recurring abruptio placentae in which the infant survived.

Seventeen of the women who were again pregnant after a previous abruptio placentae that was fatal to the fetus were hospitalized prophylactically antepartum during the more recent study period for close monitoring of fetal and maternal well-being and, whenever premature placental separation was suspected, to accomplish delivery rapidly and hopefully, obtain a healthy infant. In 14 instances a live-born infant who survived was delivered without evidence of premature placental separation. In two of the pregnancies (cases I and 5, Table II) prompt identification of abruptio placentae causing fetal distress during hospitalization of the mother in the high-risk unit led to immediate cesarean delivery with infants surviving. However, in the third case (case 8) the fetus was stillborn even though the mother was hospitalized for 5 weeks, during which nonstress tests three times a week were reactive and frequent ultrasonographic evaluations demonstrated satisfactory fetal growth and an appropriate volume of amnionic fluid. This was also the unfortunate outcome in three other pregnancies in which abruptio placentae that was fatal to the fetus occurred while the mothers were hospitalized in the high-risk unit because of some complication other than previous abruptio placentae, usually mild to moderate pregnancy-induced hypertension. In two of these cases the nonstress test was reactive when performed <10 hours before fetal heart activity was discovered to be absent.

Out of 133 pregnancies subsequent to abruptio placentae fatal to the fetus, the loss of 15% of fetuses through abortion, 7% by stillbirth, and the death of one of the 83 mothers precludes any degree of optimism for subsequent reproductive attempts.

10	Gravida 4, abruptio placentae, DIC, 2235 gm infant stillborn	Gravida 5, abruptio placentae at 33 wk, DIC, mild chronic hy- pertension, 2080 gm stillborn infant	Mild chronic hyper- tension	Onset of abdominal pain 7 hr before seeking care; would more prompt care have prevented stillbirth?
11	Gravida 3, PIH, abruptio pla- centae, DIC, stillborn in- fant at 26 wk	Gravida 4, abruptio placentae 31 wk, fetal distress, CS, 1480 gm healthy infant	· _	Prompt delivery saved fetus
12	Gravida 3, 32 wk, PIH, abruptio placentae, CS, stillborn infant	Gravida 4, 29 wk, abruptio placentae, 725 gm growth-retarded stillborn infant Gravida 5, 24 wk, third fatal abruptio placentae, 620 gm stillborn infant	Tubal sterilization after fifth pregnancy; nor- motensive 1 yr after last pregnancy	Before first abruptio placen- tae fatal to fetus, she expe- rienced severe pre- eclampsia, fetal distress, and partial abruptio pla- centae at 32 wk; 1270 gm fetus was delivered promptly by CS and sur- vived

The experiences with hospitalized women who previously had severe abruptio placentae, to try to monitor fetal well-being closely and to be able to effect delivery rapidly if abruptio placentae should recur, admittedly are limited, but until there is more evidence of benefit, the expense alone is hard to justify. Instead, it is urged that effective education be provided to the pregnant woman who has had severe abruptio placentae previously, to her family, and to all of the members of the obstetric staff who participate in her care. The serious risks associated with a subseqent pregnancy, the need to see care immediately, day or night, whenever abdominal pain, low back pain, or vaginal bleeding develops, and the need at times for immediate delivery require emphasis.

Is a recommendation of deliberate preterm delivery justified on the basis that during two periods of time a previous abruptio placentae fatal to the fetus predestined recurrent placental separation and stillbirth for 7% of subsequent pregnancies? If so, how remote from term? Delivery of all such pregnancies once the fetus achieved a weight of 2000 gm would have yielded a live-born infant in one half the cases in both our studies. At the same time prematurity would have been imposed deliberately on nearly 90% of pregnancies in which abruptio placentae fatal to the fetus was not destined to recur. Even so, preterm delivery should be considered once serious complications from prematurity are unlikely. By so doing, perhaps two of the eight fetal deaths from recurring abruptio placentae in the current study and three of the 10 deaths in the earlier study might have been avoided. Moreover, maternal morbidity and mortality even with cesarean delivery are likely to be less when delivery is accomplished under well-controlled conditions rather than the hectic state often imposed by abruptio placentae with fetal and maternal distress.

Trauma. In only three instances was abdominal trauma implicated in the genesis of abruptio placentae fatal to the fetus. In each case, even though the mother was wearing a seat belt, the abdomen struck the steering wheel forcefully during an auto accident, causing in two of the cases a sizable laceration of the placenta with severance of overlying fetal vessels and lethal fetoplacental-to-maternal hemorrhage. Both cases are considered further under "Fetoplacental hemorrhage."

Even though Parkland Hospital is a major trauma center for the greater Dallas region, in both studies external trauma was rarely identified as the probable cause of abruptio placentae fatal to the fetus. External trauma was implicated etiologically only five times in our two studies, involving a total of 408 cases so severe as to kill the fetus. During this same time, births at Parkland Hospital exceeded 250,000. These findings deserve emphasis for medicolegal reasons alone.

Fetoplacental hemorrhage. Three instances of massive fetoplacental-to-maternal hemorrhage were identified. Two, mentioned above, were in women who struck the steering wheel with enough force to lacerate the placenta, and the third had a septate uterus. Red blood cells resistant to acid elution, equivalent to 30% to 70% of the normal red blood cell content of the fetoplacental circulation, were identified in the maternal circulation.

In 78 additional cases of severe abruptio placentae, erythrocytes containing hemoglobin F were sought in smears of maternal blood. In 61 instances (80%) no hemoglobin F-containing cells were seen at inspection of \geq 4000 red blood cells per slide. In the 17 instances in which smears were positive, the volumes of red blood cells rich in hemoglobin F in the maternal circulation were estimated according to the formula of Mollison⁶ to be <10 ml. Most likely, red blood cell loss of this magnitude from the fetoplacental circulation into the maternal circulation did not contribute to fetal death.

These observations imply that hemorrhage from the fetoplacental circulation is most likely to be a major factor in fetal death in circumstances in which the abdomen has been subjected to considerable force and, in turn, the placenta has been actually lacerated, as in the two trauma cases cited above. Otherwise, life-threatening fetoplacental-to-maternal hemorrhage did not appear to be a factor in fetal death.

Premature rupture of membranes. In two instances of gross hydramnios, abruptio placentae with brisk vaginal bleeding soon followed spontaneous rupture of the membranes and the rapid escape of massive volumes of amniotic fluid. An anencephalic fetus in one case and a hydrocephalic fetus in the other died in utero. Most likely the rapid decrease in the size of the uterine cavity, including the retroplacental uterine surface to which the placenta had been attached, served to shear off the placenta, just as delivery of the fetus normally does. In our earlier study we identified one case of marked hydramnios with rupture of membranes and acute abruptio placentae. Preterm premature rupture of the membranes in the absence of gross hydramnios was identified only twice in these 207 cases.

In at least three reported studies preterm premature rupture of the membranes has been implicated in the genesis of abruptio placentae, even in the absence of gross hydramnios or other recognized predisposing factors. 7-9 In the absence of hydramnios, however, we found little evidence that premature rupture of the membranes is likely to result in severe abruptio placentae. To reduce maternal discomfort and enhance the quality of labor in pregnancies complicated by severe hydramnios, it has been our policy as prophylaxis to drain off slowly approximately one half the estimated volume of fluid transabdominally. This policy has minimized the risk of sudden, massive decompression of the uterus and severe abruptio placentae after spontaneous rupture or transvaginal amniotomy.

Maternal folate and iron deficiencies. A flurry of

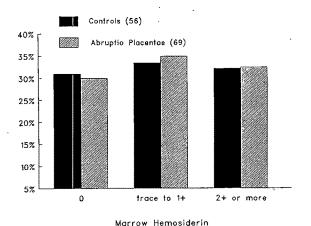

Fig. 2. Maternal storage iron identified histochemically as hemosiderin.

reports, in the 1960s and 1970s especially, implicated folic acid deficiency in the genesis of abruptio placentae, but several other studies failed to affirm a relationship. Nonetheless, the impression that abruptio placentae can be a consequence of folic acid deficiency has persisted in some quarters.

We investigated still another characteristic feature of abnormal folate metabolism, namely, maternal red blood cell macrocytosis in women with severe abruptio placentae. Mean corpuscular volume was measured electronically on a sample of blood obtained before transfusion from 175 women with abruptio placentae sufficient to kill the fetus; the results were compared with those obtained from 186 control women admitted for routine delivery. Neither group was given supplemental folic acid prenatally. The mean corpuscular volume averaged 89.0 fl for the women with severe abruptio placentae compared with 89.1 fl for the control group.

Since coincidental iron deficiency might mask macrocytosis from folate deficiency, iron stores of 64 women with severe abruptio placentae and 56 who were admited for routine delivery were evaluated histochemically as hemosiderin in bone marrow aspirates obtained during earlier extensive studies of folate and iron metabolism in late pregnancy. As shown in Fig. 2, iron deficiency was no more common in women with severe abruptio placentae than in the general obstetric population.

Neither folic acid nor iron deficiency is an important factor in the genesis of severe abruptio placentae.

Uterine anomaly or tumor. In two instances of severe abruptio placentae a septate uterus was observed. The only women in whom uterine leiomyomas was identified underwent hysterectomy 1 month after experiencing abruptio placentae that was fatal to the fetus. None of the myomas were submucous.

As in our earlier study, evidence is lacking to impli-

cate uterine anomalies or myomas as a frequent cause of severe abruptio placentae. Rice et al., 10 however, recently reported a frequency of 10.8% for abruptio placentae of all severities in pregnancies of women with leiomyomas, but even more recently Davis et al. 11 reported no instances of abruptio placentae in an anterospective study of 85 pregnant women with uterine leiomyomas. The results of our studies are in agreement with those of Davis et al.

Comment

The reduction by almost 50% in the frequency of severe abruptio placentae at Parkland Hospital from 1 in 420 deliveries during 1956 through 1969 to 1 in 830 from 1974 to 1990 can be attributed for the most part to two major changes observed in the obstetric population. There has been a dramatic decrease in the number of women at increased risk of severe abruptio placentae because of very high parity (≥7) and a marked increased in the number of pregnancies among Latin American women during the more recent study period. For reasons not yet identified Latin American women had severe abruptio placentae much less often (1:1473) than did white women (1:876) and especially black women (1:594). Hemoglobin S was very uncommon in black women with severe abruptio placentae and, when present, it did not appear to enhance maternal morbidity.

In both the earlier and the more recent study periods, hypertension was identified in nearly one half the women with severe abruptio placentae.

Abruptio placentae recurred in 12% of subsequent pregnancies, almost identical to the recurrence rate in the 1956 through 1969 study. It is discouraging that in more than half of the recurrences abruptio placentae again proved fatal to the fetus. The need for education of all parties involved—patient, family, and all who participate in obstetric care—is emphasized. Such education should help achieve a favorable outcome, as well as reduce the risk of medicolegal entanglements.

External trauma was recognized rarely in the genesis of abruptio placentae fatal to the fetus. Three instances involved auto accidents with a forceful blow to the abdomen. In two of the three cases the placenta was grossly lacerated with severe hemorrhage from the fetoplacental circulation, sufficient of itself to cause fetal death. Otherwise, evidence of fetoplacental-to-maternal hemorrhage that was life-threatening to the fetus was lacking.

Premature rupture of the membranes was implicated in the genesis of severe abruptio placentae in two cases of severe hydramnios with grossly ruptured membranes and rapid loss of huge volumes of amniotic fluid. Preterm prematurely ruptured membranes in the absence of hydramnios was identified rarely. Uterine leiomyomas and uterine anomalies from faulty müllerian duct fusion were rare in the 207 cases, as they were in the earlier 201 cases of severe abruptio placentae.

Abruptio placentae so severe as to kill the fetus persists as a prominent cause of fetal death.

A rapid visual test for predicting fetal lung maturity

Anthony J. Sbarra, PhD, Anjan Chaudhury, MD, Curtis L. Cetrulo, MD, Robert Mittendorf, MD, Chris Shakr, MD, Robert Kennison, MD, Johannes Jones, MD, and Joseph Kennedy, Jr., MD

Boston, Massachusetts

A rapid bedside test has been devised that enables an untrained observer to predict (p < 0.001) when amniotic fluid will be ≥ 0.15 at an optical density of 650 nm, lecithin/sphingomyelin ratio will be ≥ 2.0 , or when phosphatidylglycerol will be present. By a visual comparison of the turbidity of unspun amniotic fluid against positive (mature) or negative (immature) controls, technicians and resident physicians who had had no special training were able to classify correctly 87.2% (82/94) of unknown amniotic fluid samples. The sensitivity of the new test is 90.8% (58/65); the specificity is 70.3% (23/29). Thus, when more sophisticated methods are not readily available, we believe that this easily performed and accurate test can provide supplemental or preliminary data for patient management. In remote geographic areas our method could serve as the primary source of information about fetal lung maturity. (Am J Obstet Gynecol 1991;165:1351-3.)

Key words: Fetal lung maturity, amniotic fluid turbidity, visual test

After having done >2500 determinations of optical density at 650 nm (OD₆₅₀) on spun amniotic fluid during

the past 10 years, we have found that fetal pulmonary maturity test results often could be visually predicted a priori. Amniotic fluid samples that had an $OD_{650} \ge 0.15$, a lecithin/sphingomyelin (L/S) ratio ≥ 2.0 , or phosphatidylglycerol present were usually more turbid than were immature specimens.

Because commonly used tests for lung maturity, such as those for L/S ratio and phosphatidylglycerol,¹ require laboratory support that may not be readily available in all health care settings, simpler methods have been sought by many investigators.² We felt obligated

Table I. Amniotic fluid samples with unspun $OD_{650} > 0.50$ and < 0.80

No. of subjects	Unspun OD ₆₅₀	Fetal lung maturity indices

Immature	6	23

 $[\]chi^2$ (1 df) test statistic, 46.5 (p < 0.001).

to test our hypothesis that an untrained observer could predict the outcome of fetal pulmonary maturity indices by comparing an unspun sample of amniotic fluid with known standards, one mature and the other immature.

Material and methods

In the first phase of the study 167 amniotic fluid samples were obtained by transabdominal amniocentesis for various indications and at various gestational ages. Within 2 hours of collection, OD₆₅₀ measurements were done on a Beckman DB spectrophotometer on unspun fluids with 1 cm light-path cuvettes standardized against distilled water. After the unspun optical density was recorded, samples were spun at 3200 revolutions/min (2000 g) in an International model PR-J refrigerated centrifuge for 10 minutes. The spun OD₆₅₀ was then recorded, and L/S ratios and phosphatidylglycerol analyses were performed as previously described. Specimens containing gross meconium, bilirubin, or hemolyzed blood were excluded.

From these data, positive (mature) and negative (immature) controls were determined. Because the OD₆₅₀ on unspun amniotic fluid was always \geq 0.80 when spun OD₆₅₀ was \geq 0.15, L/S ratio was \geq 2.0, or phosphatidylglycerol was present, the control for maturity was designed to mimic amniotic fluid with that level of turbidity. Because an unspun amniotic fluid OD₆₅₀ \leq 0.50 invariably was found when spun OD₆₅₀ < 0.15, L/S ratio was <2.0, or phosphatidylglycerol was absent, the immature control was designed to mimic the clearer fluid. The standards were made by dissolving purified agar in distilled water, then dispensing 8 to 10 ml of the solutions into capped Vacutainer tubes. The positive control contained 3% agar, whereas the negative

control contained 0.75% agar. The tubes were then autoclaved for 15 minutes at 15 pounds per square inch of steam pressure. After the caps were cooled, they were firmly placed and sealed with tape.

In the validation phase of the study 94 samples of amniotic fluid were collected from new patients and then compared visually with the two controls. The predictions were recorded as being mature, immature, or indeterminate. After centrifugation, spun OD_{650} , L/S ratios, and phosphatidylglycerol analyses were performed to serve as clinical standards.

Results

During the first phase of the experiment, 167 samples were analyzed. In 87 of these specimens, the unspun OD_{650} was ≥ 0.80 and the maturity indices were positive. In 32 samples the unspun OD_{650} was ≤ 0.50 and the maturity indices were negative. Thus in 119 (87 + 32) samples the standards were either mature or immature. In 48 (167 – 119) amniotic fluid specimens the outcomes were mixed; i.e., if the unspun OD_{650} was >0.50 but <0.80, the spun OD_{650} , L/S ratio, or phosphatidylglycerol could be either mature or immature (Table I).

In the validation phase, amniotic fluid samples from new patients were judged by untrained observers (technicians and resident physicians) to be positive or negative when compared with the two controls. After the evaluations, the usual lung maturity testing was performed to provide confirmation. Sixty-five amniotic fluid samples judged visually were thought to be positive. Subsequent testing confirmed that 59 of these samples were mature (Table II). Twenty-nine fluid specimens were judged visually to be negative, and 23 of those opinions were confirmed by testing. When the results were evaluated as a 2 × 2 contingency in which the laboratory indices were considered the clinical standards against which the observations were compared, the results of the χ^2 test with 1 df were highly statistically significant (p < 0.001). Thus we conclude that untrained observers who use this rapid test can accurately discriminate mature from immature amniotic fluid. The sensitivity of the test was 90.8% (59/65), the specificity was 79.3% (23/29), the positive predictive value was 90.8% (59/65) (for the validation study in which the prevalence of mature amniotic fluid was 0.69 [65/94]), and the predictive value negative was 79.3% (23/29).

Comment

The L/S ratio and phosphatidylglycerol analysis are among the most widely used tests for determining fetal pulmonary maturity. However, they require complex methods that limit their availability. Thus a number-of simpler methods have been reported. Our own re-

Volume 165 Number 5, Part 1

search laboratory introduced one of those alternatives, the spun OD₆₅₀, which has been shown to compare favorably with the L/S ratio and phosphatidylglycerol analysis in predicting the likelihood of respiratory distress syndrome in newborns.³⁻⁶ However, even spun optical density determinations require centrifugation. To improve clinical access for evaluating amniotic fluid to determine fetal pulmonary maturity, we have developed a rapid, easily performed test that needs no laboratory support. Our method requires only two turbidity tubes and a needle for amniocentesis. We have not yet validated amniotic fluid specimens obtained from vaginal pools.

Although we do not suggest that our rapid test should displace accepted laboratory standards for determining fetal lung maturity, we do believe that our simple method can be a useful preliminary assessment in many hospitals. Furthermore, in remote locales that do not enjoy the advantages of more sophisticated methods, our test (which has a 91% sensitivity and thus a 9% false-positive rate that must be considered in any clin-

ical decision-making) can provide information about pulmonary maturity when no other test is available.

Fetal abdominoscrotal hydrocele

P. Sasidharan, MD,* Stanley Crankson, MB,b and Saeed Ahmed, MBb

Riyadh, Saudi Arabia

A case of abdominoscrotal hydrocele detected initially as an intraabdominal cyst on antenatal ultrasonography is described. Abdominoscrotal hydrocele should be included in the differential diagnosis of antenatally recognized intraabdominal cysts and abdominal masses in the newborn. (AM J OBSTET GYNECOL 1991;165:1353-5.)

Key words: Abdominoscrotal hydrocele, fetus, ultrasonography

Antenatal maternal ultrasonography is an ideal way of evaluating pregnancy from both the obstetric and fetal points of view. Even though the precise nature of the abnormality may not be clear antenatally, antenatal recognition leads to appropriate postnatal assessment and treatment. Abdominoscrotal hydrocele is a rare condition, and there are no reports of antenatal detec-

tion of this disorder.^{1, 2} We report a case of abdominoscrotal hydrocele recognized as an intraabdominal cyst before 30 weeks of gestation that was managed surgically at 5 days of age.

Case report

Routine abdominal ultrasonography in a 28-year-old, gravida 11, para 10 woman at 22 weeks' gestation revealed a prominent cystic mass in the fetal abdomen that was thought to be a distended urinary bladder. Subsequent ultrasonography at 30 and 34 weeks' gestation revealed a fetal abdominal cyst of 5.7×4.5 cm (Fig. 1). The cyst was distinct from the urinary bladder, and the kidneys were normal. There was no evidence of any alimentary tract abnormality, and the exact na-

ture of the fetal cyst was not clear, although mesenteric cyst was considered a possibility.

The baby was born at 37 weeks' gestation by cesarean section; the birth weight was 3150 gm. Abdominal examination revealed an undistended abdomen with a soft suprapubic mass with ill-defined margins. There was also a large left inguinal swelling that could be reduced into the peritoneal cavity and was thought to be a hernia. The testes were normal. Postnatal ultrasonography and abdominal x-ray film confirmed the presence of the suprapubic cystic mass (Fig. 2). A precise diagnosis was not made, but as a result of the "hernia" early surgery was undertaken at 5 days of age. On exploration of the left inguinal canal a large cystic swelling was noted that extended into the abdominal cavity. Laparotomy was performed through a separate iliac

fossa incision when it was obvious that the "cyst" was an abdominoscrotal hydrocele that was retroperitoneal in position. The hydrocele sac extended posteriorly just lateral to the bladder, to which it was adherent. It was separated from the testicular vessels and vas and was then removed; the procedure was completed with an orchiopexy. The postoperative course was uneventful, and the baby was discharged on the fourth postoperative day. He was well and thriving at 6 months of age and had no sign of residual abdominoscrotal swelling. The testes were normal.

Comment

Abdominoscrotal hydrocele is essentially a hydrocele of the tunica vaginalis that has an inguinoscrotal and an abdominal component. Even though various etiologic theories about this condition have been proposed, the likely mechanism is that increased pressure from overdistention of an inguinoscrotal lesion produces the proximal (abdominal) herniation.^{1,2} It is also possible that the hydrocele may originate within the abdominal cavity and may extend or prolapse into the inguinoscrotal region.

Our case was unique in that the abdominal component was recognized antenatally, possibly at 22 weeks' gestation but certainly by 30 weeks. Although testicular descent normally takes place at 28 to 30 weeks' gestation, it is logical to assume that the hydrocele developed primarily within the abdominal cavity. Because the testes were in the normal scrotal position at birth, it is also likely that an abdominal hydrocele became an abdominoscrotal hydrocele by virtue of increased pressure within the abdominal component and downward displacement. It would also appear that with the increasing use of ultrasonography, both antenatally and postnatally, an "abdominal" hydrocele without an inguinoscrotal component may be seen.

Although abdominoscrotal hydrocele is extremely rare, it must be considered in the differential diagnosis of a lower abdominal cystic mass in a fetus. Hydronephrosis and hydroureter also may be seen with an abdominoscrotal hydrocele.

During postnatal assessment, ultrasonography is the most appropriate investigation. In a newborn with an inguinoscrotal swelling, the abdomen should be carefully palpated. If a lower abdominal cystic swelling is palpable, pressure on the mass may produce a scrotal swelling or make it more obvious and thus lead to a clinical diagnosis of abdominoscrotal hydrocele. Treatment of this condition is total excision, and récurrence is rare unless it is not totally excised.

Editors' note

The American Journal of Obstetrics and Gynecology introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case report, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

Increased serum levels of macrophage colony-stimulating factor in ovarian cancer

F.-J. Xu, MD,^a S. Ramakrishnan, PhD,^c L. Daly,^c J.T. Soper, MD,^b A. Berchuck, MD,^b D. Clarke-Pearson, MD,^b and R.C. Bast, Jr., MD^a

Durham, North Carolina, and Minneapolis, Minnesota

Macrophage colony-stimulating factor is a cytokine that stimulates proliferation and differentiation of phagocytic cells. Macrophage colony-stimulating factor is produced by ovarian epithelial cancer cell lines and might provide a useful serum marker for the disease. Among sera from 69 patients with clinically apparent epithelial ovarian cancer, 47 (68%) had at least 2.5 ng/ml macrophage colony-stimulating factor, whereas only two of 80 apparently healthy donors (2.5%) had a comparable elevation of macrophage colony-stimulating factor. Circulating levels of macrophage colony-stimulating factor did not correlate with serum levels of CA 125. Moreover, 14 of 25 ovarian cancer patients (56%) with clinically evident disease and normal levels of CA 125 (<35 U/ml) had elevated levels of macrophage colony-stimulating factor. Among 29 patients with serum CA 125 levels <35 U/ml before positive surgical surveillance procedures, 9 (31%) had at least 2.5 ng/ml macrophage colony-stimulating factor. Elevated levels of macrophage colony-stimulating factor were also found in patients with carcinomas from other primary sites and in 31% of 134 patients with benign diseases. If intercurrent benign disease can be taken into account, macrophage colony-stimulating factor deserves further evaluation in combination with CA 125 in monitoring ovarian cancer. (AM J OBSTET GYNECOL 1991;165:1356-62.)

Key words: Tumor marker, macrophage colony-stimulating factor, cytokines, ovarian carcinoma, renal failure

Tumor cells produce growth factors, some of which may regulate the proliferation of cancer cells by autocrine and paracrine pathways.1-7 The aberrant overexpression of a trophic factor by cancer cells can relate to gene amplification or to a genetic translocation that brings a growth factor gene under the control of different regulatory elements. Interestingly, colony-stimulating activity has been detected in a number of nonhematologic tumors.6,7 Concomitant with the expression of colony-stimulating factor (CSF) activity, higher levels of circulating leukocytes have been seen in some of these patients.4.5 Both clinical observations and studies of human tumor xenografts in nude mice indicate that cytokines can be produced constitutively by malignant cells.7 Although the importance of these factors remains uncertain, cytokine levels in serum may provide markers that can be used to detect tumor growth and to monitor treatment response.

In a recent study we reported that each of six ovarian cancer cell lines secreted macrophage CSF into the culture medium in the absence of any external stimuli.8 Although lymphoid and myeloid cell lines failed to produce detectable amounts of macrophage CSF, a limited number of breast cancer cell lines secreted the factor in significant quantities. The presence of macrophage CSF was confirmed by immunologic and biologic assays and by analyzing total cellular ribonucleic acid for macrophage-CSF-related transcripts.8 Kacinski et al.9 have detected the expression of macrophage CSF transcripts in ovarian carcinoma cells and ovarian adenocarcinomas express fms complementary transcripts and fms antigen.9, 10 Macrophage CSF also has been found in plasma from patients with ovarian, endometrial, mammary, and pulmonary carcinoma.11-13

Macrophage CSF is a dimeric glycoprotein of about 70 kd, it belongs to a group of cytokines that regulate the ontogeny of blood cells. Macrophage CSF selectively stimulates proliferation and differentiation of both monocyte precursors and mature macrophages. As a result of our earlier finding that macrophage CSF is produced by ovarian cancer cell lines ex vivo, we investigated whether patients with ovarian cancer have an increased level of macrophage CSF in serum. An earlier study reported that macrophage CSF levels were elevated in ovarian cancer patients that included a small subset of patients monitored longitudinally in and whom macrophage CSF was elevated

at recurrence without a simultaneous elevation of CA 125. We were especially interested in determining the frequency of macrophage CSF elevation in a larger number of ovarian cancer patients with normal levels of CA 125 to determine whether macrophage CSF and CA 125 are complementary tumor markers for ovarian cancer. Serum samples collected from patients with well-documented disease were analyzed with a specific radioimmunoassay for macrophage CSF. We have found that macrophage CSF levels are elevated in approximately two thirds of women with clinically apparent ovarian cancer and that macrophage CSF can complement CA 125 as a marker for the presence of residual disease. This confirms and extends the studies of Kacinski et al.9,13 This is the first study to determine macrophage CSF levels in a large number of patients with various benign diseases. The highest frequency of macrophage CSF elevation among patients with benign disease was found in those with renal disease. Elevations of macrophage CSF also were observed in sera from patients with nonovarian carcinomas, such as those of the lung and endometrium (as previously reported), 12.13 as well as in patients with cervical, colon, and breast carcinomas.

Material and methods

Clinical material. A total of 104 serum samples were obtained from 91 women with advanced epithelial ovarian cancer who were treated at the Duke University Medical Center. Protocols and procedures approved by the institutional review board were followed. Among the 91 ovarian cancers there were 82 serous, 3 mucinous, I endometrioid, I mixed, 2 undifferentiated, and 2 clear cell carcinomas. The tumor was well differentiated in 7 patients, moderately differentiated in 30, poorly differentiated in 25, and undifferentiated in 3. In 26 cases differentiation was not assessed. At diagnosis, 5 patients were in stage I, 2 were in stage II, 63 were in stage III, and 20 were in stage IV. In 1 patient with advanced disease the original stage was not known. Specimens were generally obtained at later intervals, when persistent or recurrent disease was clinically evident or before second-look surgical surveillance procedures. The 14 patients from whom sera were obtained preoperatively were all in stage III or IV and had average macrophage CSF levels of 3.23 ± 1.56 ng/ml. To obtain 69 serum specimens from patients with clinically evident disease, blood samples were drawn before initial exploration in 14 patients, within 7 days after initial laparotomy in 1 patient, and at later intervals when persistent disease could be demonstrated by physical examination or radiographic procedures in 54 patients. Serum samples from 35 patients with minimal amounts of residual disease were drawn before surgical surveillance procedures. When both panels were assembled, several thousand sera were re-

viewed to select specimens with <35 U/ml CA 125, in spite of the presence of clinically evident disease or the detection of tumor during a surgical surveillance procedure.

Blood samples were also collected from 134 women with benign diseases and from 81 women with adenocarcinomas of nonovarian origin who were treated at the Duke University Medical Center. In addition, blood was drawn from 80 apparently healthy women after informed consent was obtained. Serum was separated promptly, and aliquots were stored at -70° C until

Determination of serum macrophage CSF levels by radioimmunoassay. A polyclonal antiserum was prepared in rabbits by hyperimmunization against human recombinant macrophage CSF (Genetics Institute, Cambridge, Mass.). The antiserum used in these studies has been well characterized and does not cross react with other growth factors or with cytokines such as granulocyte-macrophage CSF, interleukin-2, or interferon gamma. Details of the assay conditions have been published elsewhere.8 The assay system can detect macrophage CSF concentrations as low as 10 pg per assay tube or 200 pg/ml. To minimize interassay variation, aliquots of individual sera samples from five normal controls were used as internal standards.

Determination of serum CA 125 levels by radioimmunoassay. All serum samples from ovarian cancer patients also were assayed for the presence of the tumor marker CA 125 with an immunoradiometric method. 16, 17 CA 125 levels were expressed in units per milliliter, and the concentrations of tumor-associated antigen were correlated with macrophage CSF by means of linear regression analysis.

Results

Macrophage CSF levels in healthy individuals and in patients with benign diseases. The mean concentration of macrophage CSF in sera from a population of apparently healthy women was 1.15 ± 0.65 ng/ml. Consequently, the upper limit for the normal range of serum macrophage CSF was chosen as 2.5 ng/ml to exceed 2 SDs from the mean. The data in Fig. 1 show the range of macrophage CSF levels in the control population. Only 2 of 80 apparently healthy donors (2.5%)had macrophage CSF levels (2.65 and 3.15 ng/ml) that exceeded 2.5 ng/ml. When sera were evaluated from patients with benign diseases, macrophage CSF was >2.5 ng/ml in 42 of 134 patients (31%) (Table I). Elevations of macrophage CSF were associated with several forms of benign disease, including renal disease (78%), acute infection (50%), pulmonary disease (44%), autoimmune disease (27%), and liver disease (23%). Benign diseases were categorized as autoimmune disorders, infectious processes, lung diseases, renal diseases, liver disease, and benign breast conditions. Au-

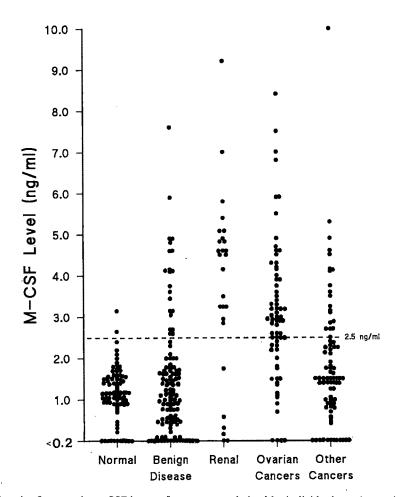

Fig. 1. Levels of macrophage CSF in sera from apparently healthy individuals, patients with benign diseases, ovarian cancer patients, and patients with a variety of nonovarian cancers. Each value is mean for triplicate determinations. Values in parentheses indicate number of samples analyzed.

Table I. Elevation of macrophage CSF (>2.5 ng/ml) in women with benign diseases*

Disease group	No. elevated per No. studied	%	Mean ± SD	Range (ng/ml)
Renal disease	21/27	78	3.58 ± 2.09	0.01-9.20
Hepatic disease	3/13	23	1.89 ± 1.99	0.01-7.60
Autoimmune disease	6/22	27	1.59 ± 1.35	0.01-4.90
Pulmonary disease	7/16	44	2.11 ± 1.68	0.01-4.90
Acute infection	5/10	50	2.88 ± 1.63	0.58-5.90
Benign breast disease	0/46	0	0.91 ± 0.66	0.01-2.00

*Elevations of macrophage CSF were associated with renal failure (n = 12), lupus nephritis (n = 4), polycystic kidney disease (n = 1), diabetic nephropathy (n = 1), nephrotic syndrome (n = 1), renal calculus (n = 1), cirrhosis (n = 2), hepatitis (n = 1), severe rheumatoid arthritis (n = 4), systemic lupus erythematosus (n = 2), chronic obstructive pulmonary disease (n = 3), Wegener's granulomastosis (n = 1), probable tuberculosis (n = 1), pulmonary alveolar proteinosis (n = 1), pulmonary mucormycosis (n = 1), pneumonia (n = 1), peritonitis (n = 1), staphylococcal sepsis (n = 1), urosepsis (n = 1), and fever of unknown origin (n = 1).

toimmune disorders included rheumatoid arthritis (n = 10); systemic lupus erythematosus (n = 4); Sjogren's syndrome (n = 2); multiple sclerosis (n = 3); myasthenia gravis (n = 1), psoriatic arthritis (n = 1), and autoimmune hemolytic anemia (n = 1). Infectious

processes included cellulitis (n = 2), pneumonia (n = 2), sepsis (n = 3), peritonitis (n = 1), and skin abscess and gangrene of the foot (n = 1). Benign lung diseases included chronic obstructive pulmonary disease (n = 6), asthma (n = 3), Wegener's granulomatosis (n = 1),

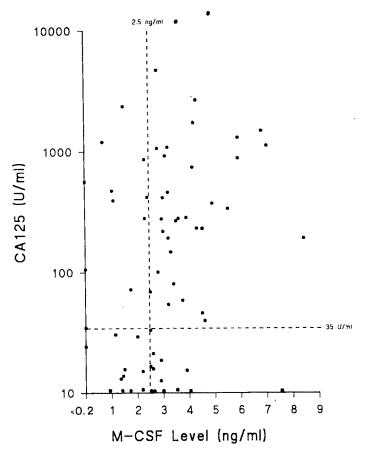

Fig. 2. Correlation between macrophage CSF levels and CA 125 levels in serum. Macrophage CSF and CA 125 were measured in serum samples obtained from ovarian cancer patients. Horizontal line demarcates 35 U/ml (value of CA 125 used to distinguish 99% of apparently healthy individuals). Vertical line indicates 2.5 ng/ml that exceeds mean level of macrophage CSF by 2 SD for healthy control population.

tuberculosis (n = 1), pneumonia (n = 1), histoplasmosis (n = 1), pulmonary alveolar proteinosis (n = 1), pulmonary mucormycosis (n = 1), and interstitial lung disease (n = 1). Renal diseases included lupus nephritis (n = 5), nephrotic syndrome (n = 3), nephrolithiasis (n = 3), polycystic kidney disease (n = 1), diabetic nephropathy (n = 1), renal stricture and obstruction (n = 1), and renal artery stenosis (n = 12). Liver disease included cirrhosis and hepatitis. Benign breast conditions included fibrocystic changes (n = 10), fibroadenomas (n = 7), chronic mastitis or abscess (n = 2), and various forms of dysplasia, hyperplasia, fibrosis, and duct ectasia (n = 10). Among the patients with renal disease, all 12 with renal failure had elevated levels of macrophage CSF. However, no elevations of macrophage CSF levels were observed among 46 patients with benign breast disease.

Serum macrophage CSF levels in ovarian cancer patients. As a result of our previous observation that ovarian cancer cell lines secrete macrophage CSF constitutively, it was of interest to find whether the levels

of this factor could be elevated in sera from ovarian cancer patients. Sera from 69 women with clinically apparent ovarian cancer were analyzed (Fig. 1). The mean value of macrophage CSF among these cancer patients was 3.02 ± 1.72 ng/ml, which was approximately 2.6-fold higher than the mean value of the control group. The values were distributed over a wide range from <0.2 to 8.4 ng/ml. Further analysis of the data indicated that 47 of the 69 cancer patients (68%) had macrophage CSF levels >2.5 ng/ml, which is an increase that is statistically significant (p < 0.001) when compared with levels in sera from healthy controls.

Comparison of macrophage CSF and CA 125. All serum samples from ovarian cancer patient were analyzed for CA 125 levels.17 In the current series 10 of the 69 samples had very low levels of CA 125 (<10 U/ml) and 12 samples had >1000 U/ml. To determine whether any correlation existed between CA 125 levels and macrophage CSF levels, paired values were plotted (Fig. 2). No definite relationship was found between serum levels of macrophage CSF and CA 125. In es-

Table II. Elevation of macrophage CSF (>2.5 ng/ml) in women with nonovarian carcinoma

	Eleva	ited	Many (CD	.*
Primary site	No.	. %	$Mean \pm SD = (ng/ml)$	Range
Breast carcinoma	10/54	· 18	1.38 ± 1.19	0.01-4.90
Lung carcinoma	2/6	33	2.39 ± 1.15	0.42-3.60
Colon carcinoma	3/8	38	3.06 ± 2.95	1.25-9.99
Endometrial carcinoma	3/6	50	2.60 ± 1.61	0.98-5.30
· Cervical carcinoma	3/7	43	1.98 ± 1.85	0.01-4.60

tablishing the panel for patients with clinically evident disease, several sera had been selected intentionally bècause CA 125 was <35 U/ml. Only 64% of 69 patients with clinical evidence of disease had CA 125 values >35 U/ml. In the same group of sera, elevated macrophage CSF levels (>2.5 ng/ml) had been found in 68%. Significant complementarity was observed between the two markers. Fourteen of 25 ovarian cancer patients (56%) with clinically evident disease and normal levels of CA 125 (<35 U/ml) had elevated macrophage CSF (>2.5 ng/ml). Sera were available from 37 patients in whom residual disease had been found at surgical surveillance procedures. CA 125 was >35 U/ml in 9 of these patients, (24%) and macrophage CSF was at least 2.5 ng/ml in 15 (40%). Among the 29 patients with serum CA 125 <35 U/ml before positive surgical surveillance procedures, 9 (31%) had at least 2.5 ng/ml macrophage CSF. We have compared macrophage CSF levels in patients with clinical evidence of disease with macrophage CSF levels in patients with disease detected at secondlook surgery to determine the possible effect of tumor burden on the macrophage CSF level. Patients with clinical evidence of disease (mean macrophage CSF level, 3.04 ± 1.83 ng/ml) had significantly higher macrophage CSF levels (p < 0.043, Student t test) than did patients whose disease was detected at second-look surgery (mean macrophage CSF level, $2.29 \pm 1.33 \text{ ng/ml}$).

Elevation of macrophage CSF in nonovarian carcinomas. Macrophage CSF levels were elevated in a variety of nonovarian carcinomas (Table II). A fraction of patients with endometrial (50%), cervical (43%), lung (33%), and colon (38%) carcinomas had at least 2.5 ng/ml macrophage CSF in sera. Elevated levels of macrophage CSF were observed in 10 of 54 patients (18%) with clinically evident breast cancer but in none of 8 patients without evidence of disease recurrence.

Comment

In the absence of malignancy macrophage CSF is produced constitutively by a variety of cells that include fibroblasts and endothelial, epithelial, and placental cells. 8, 18, 19 Certain functionally differentiated cells such as monocytes do not secrete detectable quantities of macrophage CSF unless they are stimulated with phorbol esters or with bacterial lipopolysaccharides. 20, 22 Nor-

mal serum contains some basal amount of colony-stimulating factor.23 A recent report by Shadle et al.24 indicated that sera from a limited number of subjects contained a mean macrophage CSF level of 1.5 ng/ml. The steady-state level of macrophage CSF in serum is governed by the rates of production and clearance. Although the rate and compartments involved in the clearance of macrophage CSF have not been completely resolved, Kupffer's cells and alveolar macrophages may contribute to the removal of macrophage CSF from the circulation by means of specific receptors.25 Macrophage CSF has a very short half-life, and injection of radioiodinated macrophage CSF is quickly cleared from the circulation within 15 minutes. The markedly elevated levels of macrophage CSF observed in patients with renal failure in this study suggest that the renal clearance or metabolism of macrophage CSF deserves further evaluation. Alternatively, processes associated with dialysis or end-stage renal disease might stimulate the production of macrophage CSF.

Elevated serum levels of macrophage CSF were observed in 68% of patients with epithelial ovarian cancer and in a smaller fraction of patients with several other types of carcinoma. The range of concentrations for the marker was relatively narrow, the mean levels in ovarian cancer patients exceeded those in apparently healthy controls by 2.6-fold. Moreover, comparable elevations of macrophage CSF were observed in 31% of patients with benign conditions, particularly renal disease, acute infection, pulmonary disease, and autoimmune disease. In spite of these potential limitations, significant complementarity was observed with CA 125, a high-molecular-weight glycoprotein that is expressed by epithelial ovarian cancers.26, 27 CA 125 has been extensively studied as a marker for monitoring ovarian cancers.28 An immunoradiometric assay that quantitates the antigen can detect from 1.4 to >10,000 U/ml of CA 125 in serum and body fluids. Approximately 99% of apparently healthy blood bank donors will have <35 U/ml of the antigen in serum, although higher values of CA 125 were found in about 6% of individuals with benign diseaes.17 Elevated levels of CA 125 are found in approximately 80% of patients with clinically evident epithelial ovarian cancer, but the remainder of patients with advanced disease have <35 U/ml of the antigen.

At the time of surgical surveillance procedures, an elevated CA 125 level (>35 U/ml) has a positive predictive value of 96%.28 In practice, however, only one patient in five will have an elevated CA 125 level, and in those ovarian cancer patients with serum CA 125 levels <35 U/ml residual disease is found at laparotomy in 40% to 60%. Use of multiple serum markers in combination might improve the sensitivity of CA 125 assays. Among ovarian cancer patients with CA 125 <35 U/ml, macrophage CSF could be detected in 56% of those with clinically evident disease. Elevated macrophage CSF was also detected in sera from 31% of patients without clinically evident disease but in whom occult disease was found at surgical surveillance procedures. Clearly, macrophage CSF deserves further evaluation as a marker for monitoring ovarian cancer patients. The limited specificity of macrophage CSF might be offset by consideration of the clinical status of the patient, as well as by the use of multiple serum markers. Recent studies suggest that the concomitant elevation of CA 125 and TAG 72 or CA 15-3 can provide a more specific test for ovarian cancer than does evaluation of the CA 125 level alone in distinguishing malignant from benign pelvic masses.29,30 After patients with an elevated CA 125 or macrophage CSF in their sera are identified, a concomitant elevation of TAG 72, CA 15-3, or other markers could be sought.

Additional studies are necessary to understand the biologic significance of macrophage CSF in epithelial ovarian cancer. Because some ovarian cancer cells express fms, the receptor for macrophage CSF, autocrine stimulation of ovarian tumor cell growth or function might occur.³¹ Alternatively, macrophages attracted by macrophage CSF to the tumor site could provide paracrine stimulation of tumor growth. Macrophage CSF can act as a chemotactic factor for macrophages³² and may be responsible for the increased number of phagocytic cells observed within some ovarian cancers. Interleukin-1, tumor necrosis factor, and interleukin-6 are produced by macrophages and can stimulate the growth of ovarian cancer cells in culture (unpublished observations). Whether this is important in vivo remains to be determined.

We thank G.L. Brown, Genetics Institute, Inc., Cambridge, Mass., for providing human recombinant macrophage CSF. We thank Dr. Robert F. O'Dea for his critical comments.

Postpartum preeclampsia-induced shock and death: A report of three cases

Jerome S. Kalur, JD, James N. Martin, Jr., MD, Kent A. Kirchner, MD, and John C. Morrison, MD

Cleveland, Ohio, and Jackson, Mississippi

Three patients with preeclampsia died as a result of prolonged postpartum hypotension that was unrelated to blood loss. Autopsy failed to reveal a cause of death. The sudden onset of hypotensive shock within 24 hours of delivery occurred in all patients, with coexistent hyponatremia present in the two patients in whom it was evaluated. These three maternal deaths appear to have occurred as a result of the previously described entity of postpartum preeclamptic shock. (AM J OBSTET GYNECOL 1991;165:1362-8.)

Key words: Preeclampsia, preeclamptic shock

In 1885 Ballantyne and Buchanan first noted that in some patients with preeclampsia "... after the completion of labour there is a great tendency to complete collapse, and that this unless checked will go on till death closes the scene." Occasional references to

"shocklike collapse" in patients with postpartum preeclampsia have appeared in the medical literature. Twenty-six years later in the United States, Bailey² reported a maternal death 2 hours post partum in a patient with eclampsia whose systolic blood pressure fell from 205 mm Hg just before birth to 100 mm Hg 27 minutes after rapid delivery and after receiving the antihypertensive *Veratrum viride*. Blood loss was reported as minimal. In 1923 Schwarz³ reported a 38.5% mortality rate for patients in whom vascular collapse occurred with preeclampsia. Driscoll¹ considered that "the most disastrous type of shock has been observed in nephritic toxemia," and he hypothesized that the

cause of postpartum preeclamptic shock involved "... changes in the chemical constituents of blood"

On the basis of a 5-year review of 1018 patients with preeclampsia at the Chicago Lying-In Hospital in 1936, Adair et al.5 noted that patients with preeclampsia often exhibited a sudden postdelivery reduction in blood pressure, then a secondary rise and a rapid fall to values lower than the initial nadir. Twenty-six patients demonstrated a drop in systolic blood pressure of ≤70 mm Hg, 16 also with "profound clinical manifestations of shock." One patient died 2 hours post partum. These cases were attributed to "vascular collapse" caused by "... altered fluid exchange between extravascular and intravascular fluids."5 Dieckmann6 noted that in such cases the hemoglobin concentration was normal, blood loss was negligible, and autopsy findings did not reveal the cause of vascular collapse.

Tatum⁷ contributed eight additional case reports in 1956 and in a subsequent article8 compared the vascular collapse associated with severe preeclampsia-eclampsia with the vascular collapse noted with acute adrenal insufficiency often complicated by low serum concentrations of sodium and chloride. One patient in Tatum's study had a serum sodium level of 112.9 mEq/L. On average, these patients with preeclampsia had mean serum sodium concentrations of 125.9 mEq/L within 2 hours of delivery; the onset of hypotension varied from 15 minutes to 24 hours after delivery. Average blood pressure during collapse was 97/57 mm Hg. All patients were treated with hypertonic saline infusions (at unspecified rates); they recovered without the characteristic second fall in blood pressure levels.8 Interestingly, a decrease in the administration rate of sodium infusion resulted in a rapid decline in blood pressure to hypotensive levels.

A recent reference to the entity of postpartum preeclamptic shock was found only in one textbook,9 and there appear to have been no further case reports. Indeed, references to this syndrome have been deleted from recent texts because there has been a general reduction in maternal mortality among patients with hypertension complicating pregnancy. The dearth of recent reference to preeclampsia may have led to a lack of appreciation of this rare entity.

The purpose of this article is to document three recent fatal cases of postpartum preeclamptic shock and to discuss the diagnostic criteria and presumed pathogenesis of this complication. In two of the three cases litigation led to the correct diagnosis after plaintiffs' attorneys sought to use below-standard-of-care explanations for the then-unexplained deaths.

Case reports

Case 1. A 34-year-old gravida 2, para 1 woman was admitted at 34 weeks' gestation with an initial blood pressure of 160/120 mm Hg. Conservative manage- ... ment led to rapid stabilization and a continuation of pregnancy for 10 days. At that point the fetal biophysical profile began to deteriorate and delivery by cesarean section was elected after the patient was stabilized with magnesium sulfate. During the 24 hours before delivery blood pressure readings varied between 156/100 and 160/106 mm Hg. The abdominal delivery was uneventful, yielding a viable female infant. Blood loss was normal. The patient's blood pressure immediately after delivery was 160/100 mm Hg. Postoperative medications included intravenous magnesium sulfate (1 gm/hr), phenobarbital 100 mg intramuscularly every 8 hours, hydralazine 10 mg for blood pressure >160/100 mm Hg, meperidine 100 mg every 4 hours as needed for pain, and promethazine 25 mg every 4 hours as needed for nausea.

Hydralazine was administered 41/2 hours after delivery when blood pressure increased to 189/116 mm Hg. The rate of intravenous fluid administration was >100ml/hr, and urine output averaged >25 ml/hour. Hematocrit was 35%, and platelet and liver enzyme counts were normal. Nine hours after delivery, the patient was fully awake and conversing with the nursing staff. Thirteen hours after delivery blood pressure was 143/100 mm Hg, and 100 mg of meperidine was administered intramuscularly for pain relief. Fourteen and one-half hours after delivery blood pressure was 90/46 mm Hg, reflexes were 2+, and urine was trace for protein and 2+ for blood. Urine output was adequate. The maternal pulse increased from 100 beats/min 11 hours after delivery to 153 beats/min 14 hours after delivery. At 14% hours after delivery blood pressure decreased to 78/49 mm Hg and pulse decreased to 133 beats/min. The patient responded to painful stimuli only. After aggressive intravenous resuscitation the patient's blood pressure 15 hours after delivery was 114/70 mm Hg.

One hour later the patient's blood pressure precipitately decreased to 78/49 mm Hg, with a pulse of 133 beats/min and respirations 12/min. Two minutes later, blood pressure decreased further to 62/24 mm Hg; the patient remained unresponsive in spite of prolonged efforts to resuscitate her. Serum electrolyte concentrations were not obtained before the patient's death.

An autopsy failed to reveal any anatomic cause for the patient's sudden deterioration and death. Focal edema and small alveolar hemorrhages were found in the lungs. The liver also demonstrated mild focal edema. These changes were attributed to hypotension. Because of the short interval between the severe hypotensive episodes and death, changes were not evident in the brain and no evidence of swelling or herniation was observed. Evidence of disseminated intravascular coagulation was not found. Table I and the Appendix. show clinical and autopsy findings.

Case 2. A 23-year-old primigravid woman was found at her 36-week prenatal visit to have blood pressure of 154/94 mm Hg and nondependent edema; urine reaction for protein was 1+. In spite of bed rest, 10 days later the patient had blood pressure of 140/92 mm Hg and worsening edema; urine reaction for protein was 2+. Spontaneous labor ensued 2 days later, with blood

pressure 170/108 mm Hg and moderate hyperreflexia; urine reaction for protein was 4+. Magnesium sulfate at 1 gm/hr was infused intravenously. After a 6½-hour labor course, a viable infant was delivered. After the placenta was delivered the patient's blood pressure decreased precipitately from 160/105 to 60 mm Hg/palpable. Simultaneously, the patient's pulse rose to 130 beats/min.

The combination of vigorous cardiorespiratory resuscitation, fluid administration, and dopamine infusion caused a rise in blood pressure to 120/70 mm Hg over the next hour. However, a second decrease in blood pressure to 66 mm Hg/palpable and an increase in pulse to 146 beats/min occurred 30 minutes later. The patient received 500 ml of normal saline solution and 600 ml of 5% dextrose in normal saline solution for resuscitation. Soon thereafter the patient regained consciousness but was unable to move the extremities on her right side. A serum sodium level obtained 15 minutes after the initial hypotensive episode was 125 mEq/L.

Approximately 12 hours post partum the patient became hypotensive, with a 100 mm Hg decrease in systolic pressure within 25 minutes. Resuscitation efforts with hypertonic saline infusions did not restore blood pressure to adequate levels for 1½ hours. A sustained decrease in systolic pressure occurred over a prolonged interval. Normotensive levels were attained only after the serum sodium concentration was normalized. However, the patient died because of ischemic complications from the two prolonged hypotensive episodes.

Autopsy revealed extensive ischemic damage to the small intestine, lungs, kidneys, and brain. Infection had spread throughout the body as a result of bacterial infiltration through ischemic intestinal walls. Death ultimately resulted from adult respiratory distress syndrome. Examination of the brain was refused, although computed tomographic scan had revealed ischemic watershed infarctions (Appendix).

Case 3. An 18-year-old primigravid woman at 36 weeks' gestation had no prenatal complications until 1 week before admission. At admission she had blood pressure of 140/90 mm Hg and trace nondependent edema; urine reaction for protein was 3+. In spite of bed rest, 3 days later she had blood pressure of 140/95 mm Hg and worsening edema; urine reaction for protein was 2+. Induction of labor was undertaken in association with intravenously administered magnesium sulfate at 1 to 2 gm/hr. Urinary output remained >25 ml/hr. Serum electrolyte levels were normal, including a serum sodium level of 137 mEq/L. After only a 51/2-hour first and second stage of labor a 2370 gm male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively, was delivered with low forceps. In the postpartum recovery area the patient continued receiving magnesium sulfate at 2 gm/hr. Urinary output initially averaged 70 ml/hr, and vaginal bleeding was not excessive. Immediate postpartum hematocrit was 36%, hemoglobin concentration was 12 gm/dl, and platelet counts and liver enzyme activity were normal. Nine and one-half hours after delivery the patient had a precipitous drop in blood pressure to 60/40 mm Hg over a 15-minute period in spite of having previously averaged 140/92 mm Hg. The patient became combative and was thought to have seizure activity. A 4 gm bolus of magnesium sulfate was infused immediately, and the seizure activity subsided. Blood drawn at the time of seizure revealed a serum magnesium level of 4.8 mg/dl and normal liver function studies; electrolytes were normal with the exception of the serum sodium level, which was 122 mEq/L. The patient had received 1.8 L of 5% dextrose in water and 0.9 L of 0.5N saline solution during labor.

After anticonvulsive and hypotensive therapy, the patient's blood pressure and pulse increased to 120/70 mm Hg and 96 beats/min, respectively, during a 45-minute interval. Infusion of normal saline solution was continued; however, 1½ hours later a second drop in

blood pressure to 40 mm Hg/palpable was noted, and the patient became unresponsive. Multiple efforts at resuscitation were unsuccessful, and the patient was pronounced dead approximately 12 hours after delivery. Permission for autopsy was refused.

None of the three patients had a history of renal disease or hypertension. Serum creatinine concentrations as a reflection of renal status were within normal limits during the prenatal period. In no instance was excessive (>2 L/24 hr) hypotonic intravenous fluid administered, nor were fluids severely restricted. Serum potassium and glucose values obtained around the time of the hypotensive episodes (cases 2 and 3) were within normal limits.

Comment

Preeclampsia, especially in its severe form, is characterized as a state of increased cardiac output, vascular reactivity, and peripheral vascular resistance.10 A redistribution of intravascular volume into the extravascular space occurs with resultant decreased plasma volume but normal pulmonary capillary wedge and central venous pressures. A derangement of cellular sodium homeostasis is considered to play a considerable role in the pathophysiologic development of preeclampsia." Unfortunately, detailed sequential antepartum electrolyte studies in women with a tendency to develop preeclampsia do not exist, although the hemoconcentration usually observed in these subjects is associated with normal serum sodium concentration in most patients. 12

The subjects described in this report and those sporadically described since 1885 suggest that there is a small subset of women with preeclampsia whose postpartum mobilization of fluid and sodium from the extravascular space is delayed. Low serum sodium concentrations develop in association with hypotensive episodes; such patients are unlikely to survive unless there is rapid infusion of a hypertonic saline solution as proposed by Tatum.7 It is unknown why a small number of patients with severe preeclampsia fail to mobilize and maintain sufficient serum sodium concentrations during the early postpartum period, thereby precipitating vascular collapse and shock. The reason could be related to adrenal corticosteroid production. Tatum theorized that after delivery there may ensue an acute period of adrenal cortical insufficiency that disrupts the process of rapid extravascular-intravascular sodium movement and thereby precipitates vascular insufficiency and collapse. Studies in rabbits suggest that cerebral adaptation to hyponatremia is less efficient in females than in males.13 Unusually increased serum progesterone concentrations may participate in this differential response between sexes and among these patients because it has been shown that progesterone inhibits sodium potassium adenosine triphosphatase (ATPase) activity.14 Although most patients with severe preeclampsia have lowered plasma volume and slow but modest reductions in blood pressure post

partum, there appear to be a small number whose aberrant fluid mobilization precipitates a severe hypotensive

Review of the patients described in this report suggests that clinical severity of preeclampsia and method of delivery are unrelated to the observed vasomotor collapse. Furthermore, the hypotensive episodes associated with this syndrome are not alleviated by circulatory volume replacement alone. Thus the explanation could lie in the hemodynamic role of sodium in the vasoconstriction process. Previous authors have speculated that an aberrrant relationship between adrenal corticosteroids and low serum sodium levels could be a triggering mechanism.7.15

Caution is advised, however, with the use of hypertonic saline solution to correct symptomatic hyponatremia. Overly aggressive elevation of serum sodium concentration by >25 mmol/L in 24 hours can result in diffuse cerebral demyelinating lesions.16 Some authors now recommend that in symptomatic short-term hyponatremia the serum sodium concentration be increased rapidly only by 10%, with additional increases being achieved very slowly by water restriction. 17,18 Mortality associated with serum sodium concentrations >149 or 160 mmol/L is 40% and 60%, respectively, in elderly hospitalized patients.19 Recommendations for clinical management of symptomatic hyponatremia in gravida women with preeclampsia and vascular collapse are problematic because there exist no published clinical trials of comparative therapy. Because red blood cell Na+/K+-ATPase activity in women who are hypertensive and pregnant has been reported to be reduced in comparison to gravid women who are normotensive,20 and because efficient Na+/K+-ATPase activity in the brain is required to maintain sodium homeostasis in that organ,13 abnormal membrane cation transport may play a role in the cause of postpartum preeclamptic shock.

Autopsies of two of the three patients revealed ischemic damage to major organs as a result of acute and prolonged hypotension (Appendix). Microscopic examination of the renal glomeruli of both autopsied patients on whom autopsies were performed showed microscopic changes consistent with preeclampsia. No patient had significant hemorrhage resulting in loss of blood volume. The autopsy of the patient in case 1 revealed "no apparent anatomic cause of death." Cause of death was also indeterminate in case 2, with the principal anatomic diagnosis listed as "eclampsia, septicemia, and cerebral infarctions."

Two of the three cases were undiagnosed as to cause of death and resulted in malpractice litigation. Both the treating physicians (and thereby subsequent defendants) and the expert witnesses engaged by plaintiffs were unaware of the existence of postpartum preeclamptic shock as a complication, perhaps because of a dearth of case reports in the last 30 years and because

of the rarity of the malady. In case 1 the plaintiff claimed that the hypotensive episode occurred as a result of postoperative medications. In case 2 the bad result and organ injury with disseminated intravascular coagulation were alleged to be caused by delay of treatment with pressor agents. In neither case did the objective evidence justify such conclusions.

In summary, severe postpartum hypotension in patients with preeclampsia can ocur and result in maternal death. A high index of suspicion will allow the obstetrician to measure serum sodium, osmolarity, and perhaps cortisol levels in patients having such symptoms. Aggressive supportive measures that include the infusion of hypertonic saline solution may be helpful. Although the cause of this syndrome remains unclear, these recent patient experiences demonstrate the current necessity for obstetricians to be aware of the possibilities for such complications among patients with preeclampsia.

Appendix

Autopsy findings: Case 1

Cardiovascular system

The heart weighs 300 mg. There is no evidence of recent or old myocardial infarction. The coronary ostia on both sides are patent and the coronary arteries show no atherosclerotic thickening. The rest of the aorta and major arteries show a minimal degree of atherosclerosis. The superior vena cava and its tributaries are within normal limits, with no evidence of thrombus or embolus.

Respiratory system

The left lung weighs 340 gm and the right lung weighs 460 gm. The surfaces of the lungs are soft and pinkish gray. The dependent areas of both lungs are red-purple. The trachea and bronchi are normal. The pulmonary vasculature is normally developed, with no evidence of thrombi or emboli. Significant pulmonary edema is noted in both lungs, and a moderate degree of parenchymal hemorrhage is noted in both lungs.

Microscopic examination
Lungs: Focal atelectasis.

Genitourinary system

Kidneys: The kidneys are large, weighing 250 gm and 260 gm for left and right, respectively. The capsules of the kidneys are removed with ease and reveal a smooth reddish tan surface. Cut sections show normal corticomedullary ratio and very prominent congested medullary portion. The pelvicalyceal system is normal. Focal and segmental mesangial proliferation of the glomeruli is seen.

Appendix-Cont'd

Autopsy findings: Case 1-cont'd

Uterus: The uterus is enlarged and firm; in the uterine cavity a few blood clots are present with roughening of the mucosal surface at the site of placental implantation. The cervix is soft, congested, and dilated.

Ovaries: Normal.

Central nervous system

Brain: The calvarium shows diffuse hemorrhagic discoloration in the subperiosteal region. The dural surfaces are smooth, grayish white, and glistening. The brain weighs 1350 gm and is soft. External examination of the formalin-fixed brain shows symmetric hemispheres with normal gyrational pattern; no evidence of swelling or herniation is present. The circle of Willis shows a normal vascular distribution, and there is no evidence of atherosclerosis or other vascular abnormalities. The leptomeninges are smooth and translucent. The dural segment that is available shows pronounced ossification in several areas close to the sagittal sinus. Multiple coronal sections fail to show any abnormalities. The ventricular system is of usual size and shape. The brain is quite pale, but there are no focal lesions in the cerebral hemispheres, brain stem, cerebellum, or spinal cord.

Autopsy findings: Case 2

Cardiovascular system

The heart weighs 380 gm. There is minimal atherosclerosis of the right coronary artery. The coronary arteries are collapsed. There are minimal atherosclerotic streaks in the abdominal aorta. The vena cava and its tributaries are patent.

Respiratory system

The right lung weighs 750 gm and the left lung weighs 660 gm. The pleural surfaces are smooth and glistening, with multiple areas of hemorrhage. The bronchial mucosa is granular and green-gray. The segmental vessels of the right upper lung appear occluded by recent thrombus. There are multiple hemorrhagic infarcts in the right upper lobe. Numerous areas of the hemorrhage and congestion are present. The rest of the parenchyma shows uniform consolidation. The alveolar spaces seem to be enlarged. The pulmonary artery and veins are patent.

Microscopic examination

Main bronchus: There is almost complete necrosis of the epithelium. Abundant fungal colonies are present. There is also extensive submucosal hemorrhage.

Lungs: Multiple sections of both lungs show extensive areas of recent hemorrhage without destruction of the lung parenchyma. There are also numerous areas of necrosis with abundant polymorphonuclear cell infiltrate. Airways are filled with mucus, red blood cells, and polymorphonuclear cells. Multiple fungal colonies are present in the mucosa of the bronchi. In many areas alveolar spaces are filled with pink homogeneous, proteinaceous material and hyaline membranes. Fungal colonies are also seen in the parenchyma. On the pleural surface there is fibrin. No epithelial squames are seen. Immunohistochemical stain with the antibody against keratin did not reveal any keratin positivity in the blood vessels. Fibrin thrombi in the blood vessels are seen. There are numerous megakaryocytes in the alveolar space.

Genitourinary system

Kidney: The left kidney weighs 130 gm and the right weighs 135 gm. They are normal in shape. The glomeruli appear slightly swollen and pale. The capsule is not adherent. On removal of the capsule, the outer surface is smooth with fetal lobulations. The corticomedullary junction is normal. The calyces and pelves are normally oriented. There are multiple petechial hemorrhages on the pelvic mucosa. There is extensive tubular necrosis. Multiple granular casts are seen in the tubules. Numerous autolyzed epithelial cells are seen in the tubes. Glomeruli show widening of the glomerular basement membrane. Occasionally endothelial swelling is seen. The glomeruli appear slightly swollen.

Uterus: The uterus is markedly enlarged. It weighs 1200 gm and measures $22 \times 18 \times 9$ cm. The endometrium is hemorrhagic, and multiple irregular hemorrhagic tightly

Appendix—Cont'd

Autopsy findings: Case 2-cont'd

adherent membranes are seen. The myometrium and cervix are hemorrhagic. There are abundant partially necrotic membranes. Gram's stain reveals numerous positive cocci. Bacterial colonies are also present in the myometrium.

Ovaries: Two ovaries are present. These are enlarged with hemorrhagic surface. The left ovary measures $3.5 \times 1.8 \times 1.9$ cm and the right measures $3.7 \times 2.2 \times 1.9$ cm. The cut surface shows multiple cystic spaces measuring up to 0.5 cm in diameter.

Central nervous system

Brain: Not done.

Renal agenesis in association with malformation of the female genital tract

Pedro Acién, MD,^a José A. Ruiz, MD,^b José F. Hernandez, MD,^b Francisco Susarte, MD,^a and Angel Martin del Moral, MD^c

Alicante, Spain

Four cases of renal agenesis with an ipsilateral blind vagina and two cases with agenesis of all organs derived from one urogenital ridge are presented. These cases confirm the association of renal agenesis with these genital malformations and support the hypothesis that the embryologic development of the vagina is derived from the fused mesonephric ducts. (AM J OBSTET GYNECOL 1991;165:1368-70.)

Key words: Renal agenesis, genital malformations, embryology of the vagina

Malformations of the female genital tract can be associated with various urinary tract anomalies, but some of these anomalies are also observed in women without genital malformations. However, in cases of renal agenesis there is always an associated genital tract malformation. Detailed analysis of these malformations has allowed us to propose the hypothesis that the embryologic development of the vagina is derived from the wolffian ducts. We report six new cases of renal agenesis, four with ipsilateral blind vaginas and müllerian duplication and two with agenesis or severe hypoplasia of all organs derived from one urogenital ridge and skeletal anomalies. Table I summarizes symptoms and

some findings of the six case reports. Fig. 1 shows the schema of the urogenital tracts in these cases.

Comment

In general, all cases of unilateral blind vagina are associated with renal agenesis (or hypoplasia if there is an ectopic ureter opening into the blind vagina). On the other hand, all cases of renal agenesis are associated with blind vagina (or Gartner's pseudocyst, which is actually an atretic blind vagina) and usually müllerian duplication caused by the failure of the inductor function of the mesonephric duct.² The exceptions to the rule of renal agenesis—blind vagina are agenesis or severe hypoplasia of all organs derived from the urogenital ridge (cases 5 and 6) and some cases with partial reabsorption of the intervaginal septum, in these cases this septum is not typically present in the inferior third of the vagina.¹

Renal agenesis—blind vagina association can be caused by a lesion of the mesonephric duct (with the junction of the müllerian tubercle, the origin of the vagina) which causes there to be no opening in the

Table I. Summary of case reports

Case No.	Age (yr)	Age at menarche (yr)	Symptoms	Renal agenesis	Epithelium lining blind vagina	Skeletal anomalies
1	17	10	Abdominal pain, sudden discharge of brown, malodorous fluid at end of menstruation	Right	Cubic, monolayer, and eroded, suggesting müllerian epi- thelium	
2	18	12	Increasing dysmenor- rhea from menarche with persistent post- menstrual blood, mal- odorous discharge	Right	Eroded with chronic inflammation and focal squamous metaplasia without remnant of original epithelium	_
3	29	. 13	Large quantity of brown fluid expelled at age 16 years; cesarean sec- tion for breech pre- sentation at age 25 years; sudden puru- lent intermenstrual discharge	Left	Squamous with strong inflammatory component; inside septum were wolffian and müllerian remnants	~
4	18		Dysmenorrhea from menarche; dark, bloody postmenstrual discharge for several days; malodorous dis- charge from 6 months earlier (sexual activity)	Right	Squamous and eroded epithelium; mülle- rian remnants in- side intervaginal septum; glands lined by cubic cells	Dorsal scoliosis

Table I-Cont'd

Case No.	Age (yr)	Age at menarche (yr)	Symptoms	Renal agenesis	Epithelium lining blind vagina	Skeletal anomalies
5	43	13	Menorrhagia; large uterine leiomyomas; severe hypoplasia or agenesis of all organs derived from left uro- genital ridge	Left	_	Dorsolumbar sco- liosis
6	31	12	Cesarean section for breech presentation	Right	-	Three fused lumbar vertebrae (L-2–L- 4), severe cervico- dorsal scoliosis

urogenital sinus and no upward migration of the ureteral bud from this opening toward the metanephric blastema, which normally permits the development of the normal kidney.¹

These cases support our hypothesis that the embryology of the vagina is derived from the fused mesonephric ducts. Müller's tubercle (no ducts) would probably be required for adequate tunneling and lining, first by columnar or cubic epithelia and then epidermization. Thus the epithelium lining the blind vagina is generally of the müllerian type, but when there is transseptal communication or inflammatory alterations or when the septum is removed, the lining converts to squamous, stratified epithelia or shows squamous metaplasia. Wolffian and müllerian remnants can be found in the septum (cases 3 and 4).

Finally we must emphasize that when the symptoms of dysmenorrhea and postmenstrual bloody, malodorous discharges occur these malformations, especially the unilateral blind vagina, should be sought. Patients are usually first seen with either primary or secondary communicating uteri; through this communication a persistent infected hematocolpos can result.

The association between fetal karyotype and mean corpuscular volume

Susan L. Sipes, MD, Carl P. Weiner, MD, Katharine D. Wenstrom, MD, Roger A. Williamson, MD, and Stanley S. Grant, RN

Iowa City, Iowa

To determine whether elevated fetal mean corpuscular volume is characteristic of a chromosome abnormality or fetal disease, 22 fetuses with chromosome abnormalities, 31 with uteroplacental insufficiency, 50 undergoing their first cordocentesis for hemolytic disease, and 50 control fetuses were identified. Chromosomally abnormal fetuses had a significantly higher mean corpuscular volume than the control fetuses. Among fetuses with chromosome abnormalities, the mean corpuscular volume for trisomic or triploid fetuses was significantly higher than for fetuses with other chromosome abnormalities. An elevated mean corpuscular volume was also associated with uteroplacental insufficiency, intrauterine growth retardation, and hemolytic disease. It correlated significantly with gestational age (p < 0.002 in all cases) in all groups except trisomy or triploidy. In addition, it correlated with hematocrit in the hemolytic disease group (r = -0.60, p < 0.0001) and with Po₂ in fetuses with intrauterine growth retardation (r = -0.43, p = 0.005) from all causes including uteroplacental insufficiency. Trisomic or triploid fetuses showed no such relationships and therefore appear to have escaped the normal control mechanisms for erythropoiesis. One in 12 fetuses with an elevated mean corpuscular volume had trisomy or triploidy, whereas no fetus with trisomy or triploidy had a normal mean corpuscular volume. Thus an unexpectedly elevated fetal mean corpuscular volume in a patient undergoing cordocentesis for reasons other than evaluation of fetal chromosomes would appear to warrant further karyotypic analysis. (AM J OBSTET GYNECOL 1991;165:1371-6.)

Key words: Aneuploidy, fetus, karyotype, mean corpuscular volume

In 1986 we observed a very high mean corpuscular volume, 175.0 fl, in a blood sample obtained from a fetus ultimately shown to have trisomy 21. If a high mean corpuscular volume were characteristic of chromosome abnormalities, it could be used as an indication for karyotypic evaluation. Only one report in the literature has previously addressed this question. The results of cordocenteses performed between 1985 and 1990 in the University of Iowa Fetal Diagnosis and Treatment Unit were reviewed to determine whether a high mean corpuscular volume was typical of fetuses with a chromosome abnormality and whether other fetal diseases were associated with an elevated fetal mean corpuscular volume.

Material and methods

The study group was drawn from >300 fetuses evaluated at the University of Iowa Fetal Diagnosis and Treatment Unit for a variety of clinical indications.²

The mean corpuscular volume was determined in 267 as part of routine testing. Final diagnoses were based on antenatal and postnatal evaluation.

The technique for fetal blood sampling has previously been described in detail.² The vessel punctured is identified by (1) ultrasonographic image, (2) the direction of turbulent flow after injection of saline solution or pancuronium, (3) the presence or absence of a pulsatile waveform on a blood pressure monitor,³ and (4) pulse-gated Doppler (5 MHz transducer, GE 3600, General Electric, Rancho Mirage, Calif.) interrogation. A combination of these four techniques eliminates any question regarding the identity of the punctured vessel.

A heparinized specimen for fetal blood gas measurement was immediately analyzed (Instrumentation Laboratories, 1312 Blood Gas Manager, Lexington, Mass.). The pH, PCo₂ (millimeters to mercury) and Po₂ (millimeters of mercury) were measured directly, assuming a temperature of 37° C. A complete blood cell count was performed with a blood sample in ethylenediaminetetraacetate on automated equipment (Technicon, Tarrytown, N.Y.) and confirmed manually when necessary.

Previously published norms for umbilical venous PO₂ were recalculated with a larger sample size and gestational age epochs altered for the present study (data not shown). Norms for the mean corpuscular volume

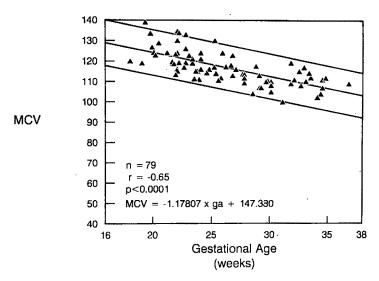

Fig. 1. Normal mean corpuscular volume (MCV) in femtoliters versus gestational age in weeks including 95% prediction intervals.

from 18 through 34 weeks were derived from 79 blood samplings on 50 control fetuses. These fetuses underwent diagnostic cordocentesis and were ultimately shown to be normal or unaffected by the disease for which they were being tested (i.e., Rh-negative fetuses in Rh-sensitized pregnancies). We defined an elevated mean corpuscular volume as being >95% prediction interval for each gestational age epoch. An abnormal umbilical venous Po₂ was defined as <95% prediction interval for each gestational age epoch.

Gestational age was determined from the earliest available fetal ultrasonographic measurements. Fetuses with intrauterine growth retardation (IUGR) met the following criteria for diagnosis⁴: (1) an antepartum ultrasonographic abdominal circumference measurement <2.5th percentile for gestational age in healthy fetuses delivered at term and (2) postpartum confirmation of birth weight <10th percentile for gestational age by an appropriate table.⁵ A subgroup of fetuses with IUGR associated with uteroplacental insufficiency was identified from within the IUGR group, after elimination of fetuses with a chromosome abnormality or documented infection.

All fetuses with abnormal karyotypes were included in the chromosome abnormality group. Although several fetuses shared this abnormality with a parent, associated fetal structural defects make the existence of microscopic deletions or duplications of chromosome material probable.

The results were presented as the mean \pm SD. Analyses were done with subroutines from Abstat rel 6.02 (Anderson-Bell, Parker, Col.). An independent t test was used to compare the gestational ages and mean corpuscular volume values between groups of fetuses. Cross tabulation with Fisher's exact test was used to

compare the percentage of fetuses with IUGR or an elevated mean corpuscular volume in the various diagnostic groups. Stepwise multiple linear regression was used with mean corpuscular volume as the dependent variable and gestational age, hematocrit, and umbilical venous Po2 as independent variables. An independent variable was added to the regression when it contributed a p < 0.1. Mean (\pm SD) mean corpuscular volume and umbilical venous PO2 values were calculated for the various gestational age epochs, using the 95% prediction intervals, where appropriate. A $p \le 0.05$ was assumed to reflect a significant difference among groups or a significant relationship among variables. Because of multiple comparisons, $p \le 0.01$ was assumed to reflect a significant difference in the multiple linear regression analysis.

Results

Four groups of fetuses were compared: control (n = 50), chromosomally abnormal (n = 22), growth-retarded in association with uteroplacental insufficiency (n = 31), and hemolytic disease (n = 50). The latter two disorders were selected because they have been associated with high mean corpuscular volume values. A second, larger growth-retarded group (n = 63) included all fetuses with available mean corpuscular volume values who fulfilled the criteria for diagnosis of IUGR (all causes).

The mean corpuscular volume values for control fetuses declined with increasing gestational age (Fig. 1). Fetuses with chromosome abnormalities (A) were significantly older than those in the control (C) group (A, 29 ± 6 weeks and C, 24 ± 4 weeks; p = 0.0008). Although the higher mean gestational age of the fetuses with chromosome abnormalities should be associated

Mean corpuscular volume elevated for gestational age (outside 95% prediction interval).

with lower mean corpuscular volume values, their mean corpuscular volume values were significantly higher than those of the control fetuses (A, 130 ± 23 fl and C, 119 ± 8 fl; p = 0.0030) (Table I).

Sixty eight percent (43/63) of growth-retarded fetuses and 46% (23/50) of fetuses with hemolytic disease had elevated mean corpuscular volume values for gestational age ($p \le 0.0001$). In the hemolytic disease group and the subgroup of growth-retarded fetuses with uteroplacental insufficiency, the mean mean corpuscular volume values were similar to those of controls, because fetuses in both groups were significantly older than the control fetuses (Table I).

On the basis of prior observations,⁶ the 22 chromosomally abnormal fetuses were subdivided into a group with either autosomal trisomy or triploidy (n = 11) and a group comprising all other chromosome abnormalities (n = 11) (Table II). The mean mean corpuscular volume for the trisomic-triploid fetuses (T) was significantly higher than the mean for fetuses with other (O)

chromosomal abnormalities (T, 142 ± 25 fl and O, 117 ± 12 fl, p = 0.0039). All trisomic or triploid fetuses (11/11) had high mean corpuscular volume values, whereas elevated mean corpuscular volume values were found in only 45% (5/11) of fetuses with other chromosome abnormalities (p < 0.025). The nonsignificant gestational age difference (T, 29 ± 5 weeks and O, 27 ± 7 weeks; p = 0.99) does not explain this phenomenon. Could growth retardation be the cause?

A high mean corpuscular volume did not correlate with growth retardation per se among the chromosomally abnormal fetuses. Although 64% (7/11) of the trisomic-triploid fetuses were growth-retarded compared with 27% (3/11) of the fetuses with other chromosome abnormalities (p=0.08), eight of the 16 karyotypically abnormal fetuses with mean corpuscular volume values that were elevated for gestational age were growth-retarded and eight were not.

Three of the fetuses in the other chromosome abnormality group could not be proved to have an un-

Table III. Elevated mean corpuscular volume—an indication of trisomy or triploidy

balanced defect, because grossly the translocation or inversion was shared with a parent. However, a microscopic duplication or deletion undetectable by present methods cannot be ruled out and seems probable in view of the associated fetal anatomic abnormalities: hydrocephalus with Arnold-Chiari malformation, myelomeningocele, ventricular septal defect, omphalomesenteric band, polymicrogyria, and small colon (case 1); polyhydramnios, severe IUGR, holoprosencephaly, pulmonary hypoplasia, hypoplastic midface, single nares, renal hypoplasia, and ambiguous genitalia (case 8); sirenomelia, sacral meningocele, atrial septal defect, bilateral renal agenesis, anhydramnios, distal tracheoesophageal fistula, and proximal esophageal atresia (case 10). Even if these fetuses are excluded from the O group (O-3), the mean corpuscular volume continues to be significantly higher in the trisomic-triploid fetuses (T, 142 ± 25 fl and O-3, 122 ± 10 fl; p = 0.023). Gestational age differences were not significant (T, 29 ± 5 weeks and O-3, 26 ± 6 weeks; p = 0.14).

Could an elevated mean corpuscular volume be useful as a test for increased risk of trisomy or triploidy? To address this question, fetuses were divided into normally grown and growth-retarded groups, since early onset IUGR is the second leading indication for karyotypic evaluation in our center. The groups were evaluated both before and after exclusion of the fetuses with hemolytic disease (Table III). The sensitivity and negative predictive value of an elevated mean corpuscular volume for trisomy or triploidy were consistently 100%, and specificity ranged from 43% to 58%. The positive predictive value ranged from 4% to 18% and was not substantially improved by exclusion of the hemolytic disease group. No fetuses with hemolytic disease had IUGR or a chromosome abnormality.

The mean corpuscular volume correlated negatively with gestational age (r=-0.51, p<0.0001) and umbilical venous Po₂ (r=-0.14, p=0.046) in all fetuses. Stepwise linear regression was applied to determine which variables had the most impact on the mean cor-

puscular volume (Table IV). The principal determinant of mean corpuscular volume was gestational age in all four groups. Mean corpuscular volume was significantly related to the umbilical venous Po2 in the uteroplacental insufficiency group. These fetuses illustrate the relationship between low Po2, IUGR, and mean corpuscular volume. Fifty-eight percent of fetuses in the study population with an abnormal Po₂ (n = 156)had an elevated mean corpuscular volume for gestational age. When fetuses with IUGR (n = 63) were excluded from the analysis, any significant relationship between mean corpuscular volume and umbilical venous Po₂ in the remaining fetuses was lost (r = -0.003, p = 0.9738). Mean corpuscular volume was significantly related to hematocrit in the hemolytic disease group. In the chromosome abnormality group, mean corpuscular volume was related only to gestational age.

When the chromosome abnormality group was subdivided by diagnosis, the trisomic-triploid fetuses had lost even the relationship between mean corpuscular volume and gestational age. Thus the normal controls of erythropoiesis and ultimately the mean corpuscular volume during fetal life no longer appeared to function in the trisomy and triploidy fetuses.

Comment

Mean corpuscular volume is higher in human fetuses than in adults and decreases with increasing gestational age.^{1, 8-10} This gestational age—dependent decline is illustrated by the control euploid fetuses (Fig. 1). In part the higher fetal mean corpuscular volume is due to an increased concentration of hemoglobin F in fetal red blood cells. Our study demonstrates that an elevated fetal mean corpuscular volume also relates to certain disease processes.

Uteroplacental insufficiency, fetal hemolytic disease, and aneuploidy have been reported to be associated with an elevated mean corpuscular volume. 1, 6, 7 Our findings confirmed these reports. However, we also noted that fetuses with autosomal trisomy or triploidy had significantly higher mean corpuscular volume mea-

surements than did fetuses with other chromosome abnormalities. It is interesting to note that all of the aneuploid fetuses in both groups (i.e., including those with mosaicism) had elevated mean corpuscular volume values. The elevated mean corpuscular volume in trisomytriploidy was at least partially independent of growth retardation. The lack of a relationship between mean corpuscular volume and gestational age, hemoglobin, and umbilical venous Po2 in fetuses with trisomy or triploidy suggests that their erythropoietic mechanism is not subject to the usual physiologic controls. This raises the possibility of using an elevated mean corpuscular volume as an indication for karyotypic evaluation.

A normal mean corpuscular volume in our study population completely ruled out fetal triploidy or trisomy (negative predictive value, 100%). The sensitivity of an elevated mean corpuscular volume for trisomy or triploidy was 100% compared with 64% sensitivity of the presence of IUGR alone for trisomy or triploidy. Early onset IUGR is the second leading indication for karyotypic evaluation in our center. This high sensitivity of an elevated mean corpuscular volume for trisomy or triploidy suggests that it may identify a higher percentage of these aneuploid fetuses than the diagnosis of IUGR alone. However there are several reasons that a fetus may have an elevated mean corpuscular volume,

as discussed previously. By including or excluding these other groups, the positive predictive value ranged from 4% to 18% (Table III). It was not substantially improved after excluding the fetuses with hemolytic disease. This positive predictive value range is compatible with the yield from screening tests such as high maternal serum α-fetoprotein (3.3%),11 low maternal serum α-fetoprotein (1.1%),12 and amniocentesis because of maternal age >35 years (<0.5%). Within a referral population similar to our study population an elevated mean corpuscular volume could be considered as a potential marker for trisomy and triploidy but not for the diagnosis of other chromosome abnormalities. Because of the relatively small sample and the fact that some of the atypical chromosome rearrangements (e.g., translocations) identified were not associated with an elevated mean corpuscular volume, we do not recommend withholding karyotypic evaluation from fetuses with a normal mean corpuscular volume.

Could the elevated mean corpuscular volume associated with these varied disease processes have a single explanation? One possibility would be decreased fetal blood oxygen content either in association with a decrease in oxygen transport (as in the fetus with uteroplacental insufficiency) or a decrease in oxygen-carrying capacity (as in the anemic fetus). The increase in erythropoiesis in severely anemic fetuses is associated with a shift toward extramedullary erythropoiesis. An increased percentage of hemoglobin F enhances the oxygen-carrying capacity of fetal blood and may occur in response to fetal hypoxia.18 Therefore, in the presence of decreased fetal oxygen content, increased extramedullary erythropoiesis and increased hemoglobin F concentration may be compensatory mechanisms. Each would result in macrocytosis. What of the fetuses with trisomy or triploidy? There was no relationship between mean corpuscular volume and either hematocrit, Po2, or gestational age in these fetuses. Perhaps red blood cell handling of oxygen or hemoglobin F concentration is abnormal in trisomy and triploidy. Identification of the ways in which their control differs from that of euploid fetuses might further define the normal control of erythropoiesis in utero.

In conclusion, the elevated mean corpuscular volume in fetuses with either IUGR, hemolytic disease, or a low Po₂ likely results from a decrease in fetal blood oxygen content. In fetal trisomy and triploidy, the mechanism may be an excess concentration of hemoglobin F or another intrinsic red blood cell abnormality. In fetuses without hemolytic disease, an elevated mean corpuscular volume indicates a fetus at increased risk for trisomy or triploidy and should lead to karyotypic evaluation.

Cytologic localization of epidermal growth factor and its receptor in developing human placenta varies over the course of pregnancy

Cecilia A. Ladines-Llave, MD,^a Takeshi Maruo, MD,^a Augusto S. Manalo, MD,^b and Matsuto Mochizuki, MD^a

Kobe, Japan, and Manila, Philippines

Cytologic localization of epidermal growth factor and its receptor in developing human placenta was analyzed by avidin-biotin immunoperoxidase techniques with a polyclonal antibody to epidermal growth factor and a monoclonal antibody to its receptor. In 4- to 5-week placenta, epidermal growth factor and its receptor were found to be almost exclusively localized to cytotrophoblasts, whereas in 6- to 12-week placentas they were predominantly localized to syncytiotrophoblasts. These findings suggest that both are initially expressed in cytotrophoblasts in very early placenta before 6 weeks' gestation and thereafter expressed in syncytiotrophoblasts in 6- to 12-week placentas. Their simultaneous expression in the cytotrophoblast of 4- to 5-week placentas and in the syncytiotrophoblast of 6- to 12-week placentas implies that epidermal growth factor may act in an autocrine manner in first-trimester placentas. By contrast, in second- and third-trimester placentas, epidermal growth factor was mainly localized to cytotrophoblasts, whereas its receptor was predominantly localized to syncytiotrophoblasts. These findings imply that epidermal growth factor may act in a paracrine fashion in second- and third-trimester placentas. The dynamic change in cytologic localization of epidermal growth factor and epidermal growth factor receptor in developing human placentas may reflect the change in a possible role of epidermal growth factor in the course of fetoplacental development. (Am J Obstet Gynecol 1991;165:1377-82.)

Key words: Placenta, epidermal growth factor, epidermal growth factor receptor, immunohistochemistry

Epidermal growth factor (EGF) is a single-chain polypeptide that is a potent mitogen in vivo and in vitro for a variety of normal and neoplastic cells.^{1, 2} It also influences differentiated cellular functions in the absence of a mitogenic effect^{3, 4} and even inhibits the growth of A431 human carcinoma cells, which contain the highest number of EGF receptors.⁵

In relation to fetoplacental development, EGF has been reported to be linked to the molura to blastocyst transformation,⁶ increased protein synthesis in trophectoderm cells of preimplantation mouse blastocyst,⁷ and successful completion of pregnancy in mice.⁸ In humans EGF has been implicated in the development

of the fetal digestive tract⁹; synthesis of prostaglandin E₂, which is involved in cervical ripening; myometrial contraction during labor¹⁰; and induction of differentiated trophoblast functions, such as production and secretion of human chorionic gonadotropin and human placental lactogen.^{11, 12}

These biologic actions of EGF are thought to be mediated by its binding to EGF receptors that are present in the target cells. The EGF receptor is known to be a glycoprotein of 170,000 d molecular weight and is present in a variety of cell types. We have immunohistochemically documented that the EGF receptor in 6- to 40-week human placentas is almost exclusively localized to syncytiotrophoblasts and that immunohistochemically detected cellular levels of EGF receptor in the placenta vary considerably over the course of pregnancy.¹³

Although placental materials are most available between 6 and 12 weeks' gestation and at term, we attempted to obtain placental tissue samples representing the entire course of pregnancy. In this study attention was focused on the expresson of EGF and EGF receptor in very early placenta before 6 weeks' gestation and the changes in cytologic localization of EGF and EGF receptor observed over the course of pregnancy. This has

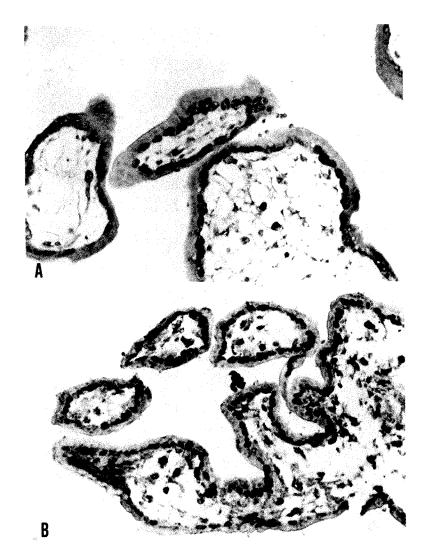

Fig. 1. Immunohistochemical localization of EGF and EGF receptor in very early first-trimester placenta. Formalin-fixed paraffin-embedded sections of 4-week placenta were stained with anti-EGF antibody (A) and with anti-EGF-receptor antibody (B). Cytotrophoblastic cells showed pronounced staining with anti-EGF antibody and with anti-EGF-receptor antibody, whereas syncytiotrophoblasts were negative for appreciable staining. (Original magnification $\times 200$.)

been discussed in relation to the possible involvement of the EGF system in fetoplacental development.

Material and methods

Materials. First-trimester placentas were obtained from 18 patients who underwent elective abortion at 4 to 5 weeks (three cases), 6 to 7 weeks (five cases), 8 to 9 weeks (six cases), and 10 to 12 weeks (four cases) of gestation. Second-trimester placentas were obtained from three patients who underwent elective abortion between 16 and 21 weeks, whereas third-trimester placentas were obtained from four patients who had cesarean section between 38 and 40 weeks. The gestational age of the placenta was determined by the known date of conception or by estimation from the date of

the patient's last menstrual period. In all cases gestational age was further evaluated by ultrasonographic examination. Informed consent was obtained before operation from the patients for the use of placental tissues for immunhistochemical studies.

Immunohistochemical staining. Placental tissues were fixed in 4% buffered neutral formalin, dehydrated, and embedded in paraffin. Sections, 5 to 6 μ m in thickness, were deparaffinized and followed by standard histologic techniques.

Immunohistochemical staining was performed by avidin-biotin immunoperoxidase techniques with the use of a polyvalent immunoperoxidase kit (Omnitags, Lipshaw, Mich.) as previously described by Maruo and Mochizuki. A rabbit polyclonal antibody against EGF

Fig. 2. Immunohistochemical localization of EGF and EGF receptor in early first-trimester placenta. Formalin-fixed, paraffin-embedded sections of 7-week placenta were stained with anti-EGF antibody (A) and anti-EGF-receptor antibody (B). Pronounced staining for EGF and EGF receptor was observed in syncytiotrophoblasts, whereas cytotrophoblastic cells were negative for appreciable staining. (Original magnification $\times 200$.)

(Collaborated Research Inc., Bedford, Mass.) and a mouse monoclonal antibody against human EGF receptor (Transformation Research Inc., Framingham, Mass.) were used as the primary antibodies in this study. The anti-EGF antibody and anti-EGF-receptor antibody were diluted 1:50 and 1:10 before use, respectively.

To assure specificity of the immunologic reactions, adjacent control sections were subjected to the same immunoperoxidase method, with the exception that the primary antibody to EGF or EGF receptor was respectively replaced by nonimmune rabbit immunoglobin G (Miles, Elkhart, Ind.) or nonimmune murine immunoglobin G (Miles). In the controls no positive staining was observed.

Results

Fig. 1, A and B, demonstrates the immunohistochemical staining for EGF and EGF receptor, respectively, in very early first-trimester placentas obtained at 4 weeks of gestation. Immunostaining with both anti-EGF antibody and anti-EGF-receptor antibody was almost exclusively localized to cytotrophoblasts. Neither syncytiotrophoblasts nor interstitial cells of placental villi showed any appreciable staining for EGF and EGF receptor. A similar pattern of cytologic localization of EGF and EGF receptor was observed in tissue sections of 5-week placentas.

Fig. 2, A and B, shows the immunohistochemical staining for EGF and EGF receptor, respectively, in early first-trimester placentas obtained at 7 weeks of

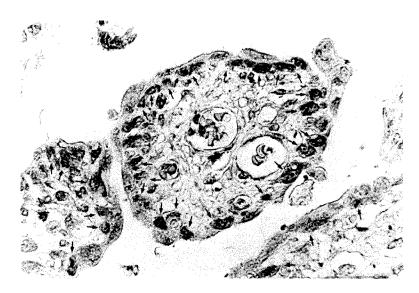

Fig. 3. Immunohistochemical localization of EGF in second-trimester placenta. Formalin-fixed, paraffin-embedded sections of 21-week placenta were stained with anti-EGF antibody. Prominent staining for EGF was observed in cytotrophoblastic cells. (Original magnification ×400.)

Table I. Immunocytologic reaction for EGF and EGF receptor in developing human placenta

			Immunostain	ing intensity

gestation. Unlike the very early first-trimester placentas obtained at 4 to 5 weeks of gestation, immunostaining with both anti-EGF antibody and anti-EGF-receptor antibody was predominantly localized to syncytiotrophoblasts. A similar pattern of cytologic localization of EGF and EGF receptor was found in tissue sections of 8- to 12-week placentas.

In the case of second-trimester placentas obtained between 16 and 21 weeks of gestation, prominent staining with anti-EGF antibody was observed in cytotrophoblasts (Fig. 3), whereas immunostaining with anti-EGF-receptor antibody has been predominantly noted in syncytiotrophoblasts.

Fig. 4 represents the immunohistochemical staining for EGF in third-trimester placentas obtained at 40 weeks of gestation. Immunostaining with anti-EGF antibody was pronounced in cytotrophoblasts, whereas immunostaining with anti-EGF-receptor antibody has been found in syncytiotrophoblasts.

The intensity of immunostaining of placental trophoblasts for EGF and EGF receptor varied over the course of pregnancy. The most pronounced staining was obtained in cytotrophoblasts of very early first-trimester (4- to 5-week) placentas and in syncytiotrophoblasts of early first-trimester (6- to 8-week) placentas. The staining intensity in second-trimester placental trophoblasts declined compared with that in first-trimester placentas, and third-trimester placental trophoblasts displayed even less staining for EGF and EGF receptor (Table I).

Comment

The data presented in this paper demonstrate that cytologic localization of EGF and EGF receptor in developing human placentas varies over the course of pregnancy. Even during the first trimester, a remarkable change in cytologic localization of EGF and EGF receptor in the placenta appeared between 5 and 6 weeks of gestation. In the very early placenta obtained at 4 to 5 weeks, EGF and EGF receptor were almost exclusively localized to cytotrophoblasts, whereas EGF and EGF receptor in early placentas obtained between

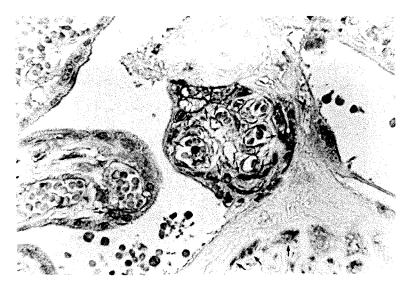

Fig. 4. Immunohistochemical localization of EGF in third-trimester placenta. Formalin-fixed, paraffin-embedded sections of 40-week placenta were stained with anti-EGF antibody. Prominent staining for EGF was found in cytotrophoblastic cells. (Original magnification ×400.)

6 and 12 weeks were predominantly localized to syncytiotrophoblasts. These findings suggest that both EGF and EGF receptor are initially expressed in cytotrophoblasts in very early placentas before 6 weeks of gestation and thereafter expressed in syncytiotrophoblasts of 6- to 12-week placentas. To our knowledge, this is the first report to demonstrate the simultaneous expression of EGF and EGF receptor in cytotrophoblasts as early as 4 to 5 weeks of gestation. The change of cytologic localization of EGF and EGF receptor in first-trimester placentas is of great interest, considering the established finding that syncytiotrophoblast is formed from cytotrophoblast by a process of proliferation followed by cell fusion.14.15

The fact that both EGF and EGF receptor in 4- to 5week placentas were localized to mitotically active cytotrophoblasts suggest that, in very early placentas before 6 weeks of gestation, EGF and EGF receptor may be linked to the proliferation of cytotrophoblasts. Although the mechanisms by which the mitogenic effects of EGF on very early placental cytotrophoblasts are mediated are unclear, it is conceivable that the mitogenic effects may be mediated by the expression of a protooncogene, c-mye. We have recently demonstrated that immunoreactive c-myc protein product appears in the nuclei of cytotrophoblasts. Furthermore, as cytotrophoblasts are in close contact with the embryonic disk,16 the predominance of cytologic localization of EGF and EGF receptor in cytotrophoblasts of very early placentas is likely to be consistent with the demands of early embryonic development as well.

On the other hand, the fact that both EGF and EGF receptor in 6- to 12-week placentas were localized to mitotically inactive syncytiotrophoblasts suggests that

EGF and EGF receptor in early placentas between 6 and 12 weeks of gestation may be involved in the induction of differentiated trophoblast function. In accordance with this, EGF has been demonstrated to stimulate human chorionic gonadotropin production by cultured early placental tissues obtained at 7 to 8 weeks of gestation.¹² Thus the predominance of cytologic localization of EGF and EGF receptor in syncytiotrophoblasts of 6- to 12-week placentas seems to relate to the formation of the peak of increased human chorionic gonadotropin production and secretion by early placenta.

The placenta is known to take over the corpus luteum function in producing progesterone and estrogen at the gestational age of 6 weeks. Before the sixth week of gestation, the corpus luteum is the prime site of progesterone and estrogen production,17 and after the sixth week of gestation the placenta becomes the main site of progesterone and estrogen production. The dynamic change of cytologic localization of EGF and EGF receptor in the placenta observed at the gestational age of 6 weeks is consistent with placental steroid hormone production at 6 weeks. This change of cytologic localization of EGF and EGF receptor from cytotrophoblasts to syncytiotrophoblasts observed in early pregnancy may reflect a possible change of the role of EGF and EGF receptor in the process of fetoplacental development. It is likely that EGF in the placenta before 6 weeks' gestation may play a major role in the induction of trophoblast proliferation and early embryonic development rather than placental hormone production, whereas EGF in the placenta between 6 and 12 weeks' gestation may play a major role in the induction of placental hormone production.

The simultaneous expression of EGF and EGF receptor in the cytotrophoblast of 4- to 5-week placentas and in the syncytiotrophoblast of 6- to 12-week placentas raises a possibility that EGF in first-trimester placentas may act in an autocrine manner. By contrast, in second-trimester and third-trimester placentas, EGF was predominantly localized to cytotrophoblasts, whereas EGF receptor was localized to syncytiotrophoblasts. This suggests that EGF in second- and thirdtrimester placentas may act in a paracrine fashion. Although the possible role of EGF and EGF receptor in second- and third-trimester placentas is still unknown, it is tempting to speculate that EGF and EGF receptor in second- and third-trimester placentas may be linked to the induction of cellular differentiation and human placental lactogen secretion, as suggested by Morrish et al.18 and Maruo et al.12 Further studies will be needed to elucidate the vital roles of EGF and EGF receptor in the fetoplacental development throughout pregnancy.

We thank Dr. Hiroshi Itoh (Department of Pathology, Kobe University School of Medicine, Kobe) for consultation and valuable suggestions during the course of this study.

Case report of myocardial infarction in labor

Nicole E. Menegakis, MD, and Marvin S. Amstey, MD

Rochester, New York

Substernal and epigastric pain occurring during labor was not considered important until the first postpartum day when an obvious myocardial infarction was diagnosed in a 37-year-old woman. Angiography revealed normal coronary arteries, and the myocardial infarction was postulated to be due to arterial spasm in association with smoking, oxytocin, ephedrine, and epidural anesthesia. (AM J OBSTET GYNECOL 1991;165:1383-4.)

Key words: Pregnancy, infarction, oxytocin, arterial spasm

Myocardial infarction during pregnancy and the puerperium is rare; its diagnosis is often overlooked because of its rarity and vague clinical presentation.

Case report

A 37-year-old white primigravid woman at 39 weeks' gestation was seen in early labor. The patient's medical history was unremarkable except for smoking one pack of cigarettes per day. She had no history of hypertension, cardiac disease, or hypercholesterolemia. She had no history of cocaine use. There were no prenatal complications when she was seen over a period of nine visits.

On admission, she was in good general health with ruptured membranes and mild uterine contractions every 5 minutes. Blood pressure was 130/80 mm Hg and pulse was 100 beats/min and regular. A grade 1/6 systolic ejection murmur was heard at the upper left sternal border. All routine laboratory data were normal. Intravenous oxytocin (Pitocin) infusion was started 8 hours after admission and reached a maximum dose of 8 mU/min. She experienced "heartburn" 21/2 hours later. This was thought to be secondary to gastroesophageal reflux and resolved with a suspension of aluminum and magnesium hydroxides (Maalox) and emesis. She received a total of 870 mU of oxytocin over this time. The infusion was stopped for an epidural anesthetic to be administered (15 ml of 0.25% bupivacaine hydrochloride [Marcaine]). Blood pressure dropped to 80/50 mm Hg with a pulse of 80 beats/min 10 minutes after the anesthetic was given; this was followed by further episodes of emesis. She was given 25 mg promethazine hydrochloride and 20 mg of ephedrine sulfate intravenously, and blood pressure returned to 100/60 mm Hg. Intravenous oxytocin was restarted, and there were no further episodes of chest pain. At

From the Department of Obstetrics and Gynecology, Highland Hospital, University of Rochester School of Medicine and Dentistry. Received for publication March 5, 1991; revised March 21, 1991; accepted April 24, 1991.

Reprint requests: Marvin Amstey, MD, Department of Obstetrics and Gynecology, Highland Hospital, University of Rochester School of Medicine, Rochester, NY 14620.

6/1/30689

12:30 AM she was spontaneously delivered of a 7 pound 5 ounce male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively.

At 1:30 AM, 2 days post partum, she complained of severe "heartburn" radiating to the back and left arm and "a large weight on her chest." She denied shortness of breath and dizziness but was diaphoretic. On physical examination, blood pressure was 150/90 mm Hg, pulse 80 beats/min and regular, respirations 16 breaths/min, and a 2/6 systolic ejection murmur at the upper left sternal border, but no third or fourth heart sounds were heard. She was treated with aluminum hydroxide and magnesium trisilicate (Mylanta) and acetaminophen and codeine phosphate (Tylenol #3). The pain, which resolved after I hour, was believed initially to have been esophagitis or musculoskeletal pain. However, an electrocardiogram done at 10:00 AM revealed an anterolateral myocardial infarction with Q waves in leads III and V2-V5, inverted T waves in lead AVL, and significant ST elevations in leads V2-V5. Echocardiogram demonstrated hypokinesis of the left ventricle. The cardiac enzyme pattern confirmed the diagnosis and suggested that the infarction had occurred 2 to 3 days previously (presumably during labor). The second episode of chest pain was presumed to be postinfarction angina. Coronary angiography was done 5 days after infarction; normal coronary arteries were demonstrated. Blood cholesterol was 250 mg/dl. The patient was treated with rest, anticoagulant therapy, warfarin sodium (Coumadin), and calcium-channel blockers (diltiazem hydrochloride). She was discharged on the eighth hospital day.

Comment

A recent review by Hankins et al. found 70 cases of myocardial infarction in pregnancy reported in the world literature. Mortality attributable to myocardial infarction in pregnancy and the puerperium is estimated to be 30% to 37%. Unfortunately, because of the rarity of the event and the age and sex of the patient, the symptoms of an impending infarction are often mistaken for more common and benign conditions typically associated with pregnancy.

The most common risk factor in young patients with

myocardial infarction is cigarette smoking. The risk of myocardial infarction in women <50 years old increases with the number of cigarettes smoked per day. Hypertension was present in 25% of patients with myocardial infarction occurring during pregnancy and the puerperium. Among patients with myocardial infarction, normal coronary angiograms are estimated at 17% for patients under the age of 36.

A likely explanation for myocardial infarction with normal coronary arteries is coronary artery spasm, the exact cause of which is unknown. The hemodynamic changes that occur in late pregnancy when the patient is in the supine position cause chorionic ischemia and may result in uterine renin release and angiotensin production with subsequent coronary artery spasm. Direct vasospastic effect of cigarette smoking on the coronary arteries has been demonstrated during angiography. The synthetic oxytocin used for this patient is devoid of vasopressin yet still has inherent pressor properties.

Evron et al.² have reported a case in which severe local arteriospasm followed infusion of the routine minimal dose of oxytocin required for postpartum uterine contraction. Therefore it is conceivable that oxytocin, given in high doses, also could cause coronary artery spasm.

The cause of this patient's myocardial infarction, in the presence of normal coronary arteries, remains unclear. Possible explanations include supine hypotension, epidural anesthesia, an injection of ephedrine, cigarette smoking, and intravenous oxytocin, each of which, individually or in combination, may have been responsible.

Endocrine effects in female weight lifters who self-administer testosterone and anabolic steroids

William B. Malarkey, MD,^{a,b} Richard H. Strauss, MD,^{a,c} Daniel J. Leizman, MD,^c Mariah Liggett, PhD,^c and Laurence M. Demers, PhD^d

Columbus, Ohio, and Hershey, Pennsylvania

It appears that the self-administration of testosterone and anabolic steroids is increasingly practiced by women in sports where strength and endurance are important. We recently evaluated endocrine parameters in nine female weight lifters using steroids and seven not using these agents. Of the nine anabolic steroid users, seven took multiple anabolic steroids simultaneously. Thirty-fold elevations of serum testosterone were noted in the women injecting testosterone. In three of these women serum testosterone levels exceeded the upper limits for normal male testosterone concentrations. A significant compensatory decrease in sex hormone—binding globulin and a decrease in thyroid-binding proteins were noted in the women steroid users. Also, a 39% decrease in high-density lipoprotein cholesterol was noted in the steroid-using weight lifters. Most of the subjects in this study used anabolic steroids continuously, which raises concern about premature atherosclerosis and other disease processes developing in these women. (AM J OBSTET GYNECOL 1991;165:1385-90.)

Key words: Weight lifers, women, testosterone, anabolic steroids, endocrine effects

The adverse effects of anabolic steroids are well described in men. These include endocrinologic (decrease in plasma testosterone and gonadotropin levels, decrease or absence of spermatogenesis, testicular atrophy, and gynecomastia), metabolic (decreased high-density lipoprotein [HDL] cholesterol, increased low-density lipoprotein [LDL] cholesterol, and hypertension), hepatic (hepatitis, cholestasis, benign and malignant tumors), and adverse psychologic effects. 1-3

The effects of androgens vary significantly among users and reflect different influences of the particular androgen preparation and individual differences in response. ^{4,5} The long-term risks of androgen use are unknown. ⁶ Also, many of these studies do not evaluate androgenic steroids as they are commonly taken, where several types of oral and injectable androgens are taken simultaneously (called stacking). This practice may produce androgen levels 10 to 100 times the replacement dose. ¹

There have been few studies in women steroid users, but the side effects that have been reported include hirsutism, deepening of the voice, hypertrophy of the clitoris, male pattern baldness, acne, menstrual abnormalities, increased aggressiveness, and, most recently, changes in lipoprotein profiles.^{7,8}

We recently had the opportunity to examine endocrinologic parameters in female weight lifters who were self-administering multiple androgenic steroids in preparation for competition.

Material and methods

Subjects. The study population consisted of nine female weight lifters using androgens and seven female weight lifters in the follicular phase of the menstrual cycle who were not using androgens (Table I). They were evaluated at The Ohio State University Clinical Research Center after informed consent and assurances of confidentiality were obtained. A patient interview, a detailed questionnaire, and a blood specimen were acquired. These women had no history of illness in the past month, other than upper respiratory infections. They were nonsmokers and alcohol intake was modest. The most frequently used steroids were methandrostenolone (Dianabol), stanozolol (Winstrol), nandrolone decanoate (Deca-Durabolin), oxandrolone (Anavar), and injectable testosterone preparations. Also used were mibolerone, methenolone acetate, trenbolone acetate, and Parabolin. These athletes obtained their steroids by nonprescription methods. A blood sample was obtained when androgen use was at its peak and also when androgen use ceased. However, only three subjects stopped steroids completely in a 12month period, for 3, 4, and 9 weeks, respectively.

Assays. Laboratory studies included a complete blood cell count and chemical analyzer measurements

of serum glucose, creatinine, blood urea nitrogen, alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, and creatine kinase. Also a lipid profile (HDL, total cholesterol, and triglyceride) was obtained with a Kodak Ectachem with barium sulfate precipitation before the HDL determination. The hormonal evaluation consisted of radioimmunoassays with standardized measurements for luteinizing hormone, follicle-stimulating hormone, estradiol, prolactin, growth hormone, dehydroepiandrosterone sulfate, sex hormone-binding globulin (SHBG), testosterone, thyroxine, and thyroid-stimulating hormone, as performed in our endocrine laboratories.9-12 Thyroxinebinding proteins were measured by fluorescence polarization (T-Uptake, Abbott Laboratories, Chicago), which provides an index as an approximation of thyroxine binding in serum. The intraassay and interassay coefficients of variation for these assays were <12%. The data were evaluated by nonpaired t tests; p < 0.05

was considered significant. Urine was not assayed for the presence of anabolic steroids.

Results

Subject characteristics. The nine weight lifters using steroids were between 23 and 41 years old (Fable I) and had been weight training 3 to 12 years. They had been using androgens for 3 months to 7 years, and all but two of the women had menstrual abnormalities (Table I). The weight-training women who were not steroid users had been weight lifting for I to 6 years and all had normal menses (Table I). The women who stated they were using three or more steroid preparations believed they had increased strength, muscle size, enhancement of training intensity, and improved performance while taking these agents. They also noted an increase in appetite, aggressiveness, irritability, sex drive, acne, deepening of the voice, body hair, and clitoral size. The serum chemistry profile demonstrated

^{*}Significantly different from controls (p < 0.05).

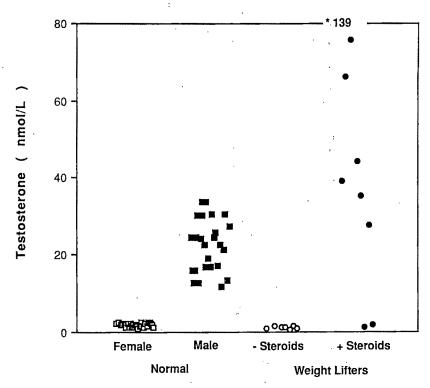

Fig. 1. Serum testosterone levels were elevated in seven female weight lifters who were injecting testosterone and were normal in two women who were using only other anabolic steroids. Note that several testosterone levels in women users were higher than those found in normal men.

mild elevations of levels of creatine kinase (in eight steroid users and two nonusers), alanine aminotransferase or aspartate aminotransferase (in four steroid users), and serum creatinine (in four steroid users) (data not shown). Other serum chemistry values were normal, including the γ -glutamyltranspeptidase and alkaline phosphatase levels.

Testosterone and SHBG levels. The most dramatic finding in the steroid users was the marked elevation in serum testosterone levels noted in seven of the nine women (Table II). The mean serum testosterone levels were 30 times those found in the non-steroid-using, weight-lifting women or in the normal female population (Fig. 1). Three of the women steroid users (subjects 2 to 4, Table II) had serum testosterone levels above the upper limits of normal for men (Fig. 1). The two women steroid users with normal serum testosterone levels were not injecting themselves with testosterone (subjects 7 and 9, Table II).

An appropriate decrease in SHBG was produced by testosterone and the other anabolic steroids (Table II). The SHBG levels (mean \pm SE) in the women weight lifters who used steroids (22.4 \pm 3.8) were significantly less than those found in normal women (57.0 \pm 4.1, p < 0.0001), women weight lifters who were not androgen users (52.5 \pm 6.4, p < 0.02), and normal men (59.6 \pm 6.5, p < 0.002) (Fig. 2). The women using the greatest number of androgen preparations (subjects 1,

3, and 8, Table I) had the lowest SHBG levels (Table II). Three women users (subjects 1-3, Table I) stopped androgens for 3 to 9 weeks. At 3 weeks the testosterone level was still elevated at 14.2 nmol/L in subject 1. At 4 and 9 weeks, however, the other subjects had normal serum testosterone levels. These latter women in whom serum testosterone levels normalized continued to have suppressed SHBG levels of 6 and 29 nmol/L.

Other endocrine measures. No significant differences (mean ± SE) in luteinizing hormone and dehydroepiandrosterone sulfate levels were found between the weight lifters who were users and nonusers of androgens, but follicle-stimulating hormone levels were significantly (p < 0.03) lower in the steroid-using women (Table II). Prolactin (users vs nonusers, 5.3 ± 0.1 and $8.0 \pm 1.0 \mu g/L$) and growth hormone (users vs nonusers, 7.4 ± 3.0 and $6.6 \pm 3.7 \mu g/L$) levels (mean \pm SE) were not significantly influenced by steroid use. The values (mean \pm SE) of total cholesterol (users vs nonusers, 4.4 ± 0.4 and 4.0 ± 0.2 nmol/L), LDL cholesterol (users vs nonusers, 3.3 ± 0.4 and 2.4 ± 0.1 nmol/L), and triglyceride (users vs nonusers, 0.8 ± 0.1 and 1.0 ± 0.2 nmol/L) were not different (Table III). The HDL cholesterol levels (mean \pm SE), however, were significantly (p < 0.05) depressed in the androgen users (users vs nonusers, 0.9 ± 0.1 and $1.5 \pm 0.1 \text{ nmol/L}$) (Table III).

levels were significantly (p < 0.05) decreased in the androgen-using women (Table IV). The thyroid-stimulating hormone level (mean \pm SE) was significantly (p < 0.001) higher in the androgen-using women (Table IV).

Comment

The major finding in this study is the marked elevation in serum testosterone levels in the female weight lifters who were injecting this sex steroid. Several of the testosterone levels obtained were higher than those usually found in normal male control subjects (Fig. 1). Their serum testosterone levels on any given day would be a reflection of the dose injected and the length of the interval between injection and blood sampling.

The biologic significance of these high levels and the other androgens not measured was documented by several lines of evidence. First, the androgen users had features of hyperandrogenism including hirsutism, increased muscular development, acne, clitoromegaly, and menstrual disturbances. Second, they had bio-

Table IV. Influence of self-administration of androgens on thyroid function tests in women

chemical changes that included a decrease in SHBG and HDL cholesterol levels.

SHBG is a protein that is produced in the liver and binds 60% of the circulating testosterone. The concentration of SHBG has been shown to be lowered by testosterone14 and other anabolic steroids15 by means of their actions on the liver. We saw similar effects in our subjects. A recent report of men taking various anabolic steroids13 and women using stanozolol and danazol14, 15 also showed a decrease in SHBG levels. Additionally, the diminished estrogen effect in seven of nine steroid users who had oligomenorrhea or amenorrhea probably contributed to the decreased SHBG levels.

Serum estradiol concentrations in the women steroid users approximated the midfollicular levels of the control women, which would be expected in oligomenorrheic and amenorrheic women. The mean follicle-stimulating hormone level of the androgen using women was suppressed (Table II), and their luteinizing hormone levels were similar to those of the controls. It is also possible that in the steroid users testosterone and the other anabolic steroids were interfering with the amplitude or number of gonadotropin-releasing hormone pulses thus producing anovulatory cycles.

Thyroxine-binding proteins also were decreased in the steroid users, as reflected by the low thyroxinebinding index and the decrease in total serum thyroxine levels (Table III). These latter changes had no significant influence on the biologic activity of thyroid hormone, however, because the free thyroxine concentration and the thyroid-stimulating hormone level were within normal limits. These findings are similar to those of a previous report of decreased thyroxine-binding globulin in men who were using anabolic steroids.13

The marked (39%) decrease in serum HDL levels in women androgen users in our study is similar to that previously reported in women and men who used steroids to enhance performance.1,8 The diminished estrogen activity that is associated with the oligomenorrhea and amenorrhea that most of the steroid users experienced probably contributed to the decreased HDL cholesterol level.

Also, the fall in HDL produced by anabolic steroids may be related to a coincidental increase in hepatic triglyceride lipase that may remove circulating HDL particles.16 The suppression of HDL cholesterol is less after testosterone injection than after the anabolic steroid regimens. It appears that the explanation for this latter observation is that the lipoprotein alterations are peculiar to the anabolic steroids with a 17α-alkylated structure.17, 18

We observed an increase in LDL cholesterol levels in the steroid users that was similar to that of previous reports,1,8 but the increase was not statistically significant (p < 0.06).

Several of the women steroid users in this study had an elevation of alanine aminotransferase, aspartate aminotransferase, and creatine kinase levels, but the alkaline phosphatase and y-glutamyltranspeptidase levels were normal. In four of these patients with the highest elevations of transaminase we also noted an increase in serum creatinine levels. Thus the evidence would suggest muscle rather than liver as the primary source of the elevation in enzymes. An increase in serum transaminase levels previously has been reported by our group in weight lifters who were not using anabolic steroids.19 This latter increase was not seen in the non-steroid-using weight lifters in this study, perhaps reflecting a less intense lifting regimen.

In conclusion, most of the subjects in this study were continuously self-administering multiple androgens, which raises concern that the abnormalities found in these women could predispose them to premature atherosclerosis and other disease processes.

^{*}Significantly different from controls (p < 0.05).

We thank the National Pituitary Hormone Program for materials used in the prolactin and growth hormone assays and the Clinical Research Center nursing staff for their assistance in this study.

The effect of gestational age on the detection rate of Down's syndrome by maternal serum α -fetoprotein screening

Frank Greenberg, MD,^{a,c} Deborah Del Junco, PhD,^c Barbara Weyland, MPH,^b W. Andrew Faucett, MS,^a Deborah Schmidt, RN,^a Esmie Rose, PhD,^b and Elliot Alpert, MD^b

Houston, Texas

Low levels of maternal serum α -fetoprotein are currently being used to screen for Down's syndrome in midpregnancy. Because of the possibility that gestational age may affect the detection rate of Down's syndrome, we analyzed maternal serum AFP levels and gestational age in 51 Down's syndrome pregnancies that had been confirmed by amniocentesis or at birth, and we compared these pregnancies with 3239 screened singleton pregnancies with known normal outcomes. The highest yield of a low risk for Down's syndrome associated with maternal serum α -fetoprotein occurred at 16.5 to 17.5 weeks' gestation. Our data suggest that maternal serum α -fetoprotein screening for Down's syndrome should be done between 16 and 18 weeks' gestation, which is the gestational age currently recommended for neural tube defect screening. (AM J OBSTET GYNECOL 1991;165:1391-3.)

Key words: α-Fetoprotein, Down's syndrome, gestational age, prenatal screening

Since the initial observation of low levels of maternal serum α-fetoprotein (AFP) that occurred in Down's syndrome pregnancies in 1984,1 low levels of maternal serum AFP in conjunction with maternal age2 have been increasingly used to screen for Down's syndrome in midpregnancy.3 Several reports have recommended that maternal serum α-fetoprotein evaluation should not be repeated after an initial low level is identified.4 This is based on observations of normal maternal serum AFP levels in second samples from Down's syndrome pregnancies after an initial low level, which is a phenomenon thought to result from regression to the mean. Because of the possibility that gestational age also may affect the detection rate of Down's syndrome, we analyzed data from the Baylor Maternal Serum Alpha-Fetoprotein Screening Program to study this question. In an earlier preliminary study we found a decrease in Down's syndrome detection rate with increasing gestational age.5

Material and methods

The Baylor Maternal Serum Alpha-Fetoprotein Screening Program is a nonprofit medical school based prenatal screening program that has been in op-

eration since 1982. Women screened by the program come mainly from the Houston area, as well as regionally. Low maternal serum AFP levels have been used to screen for increased risk of fetal Down's syndrome since 1985, and >45,000 women have been screened.

AFP was measured by radioimmunoassay with reagents from Clinical Assays, Cambridge, Mass. A more sensitive radioimmunoassay was obtained by changing the conditions of the assay to derive a standard curve from 1.0 to 50 ng/ml. The intraassay and interassay coefficient of variation at this low level was <5%. The AFP concentrations were converted to multiples of the normal median as a result of our own previous data and were adjusted for maternal weight by means of previously published formulas.⁶ A risk of Down's syndrome was then calculated by computer with the a priori maternal age risk.⁷ A cutoff risk of 1:360 at delivery was used. Gestational age was calculated by the last menstrual period unless the gestational age calculated by biparietal diameter was discrepant by >1 week.

We ascertained 52 screened Down's syndrome pregnancies since 1985. Of these 52 pregnancies, 51 were singleton gestations. Twenty-five of those women had low maternal serum AFP levels (Down's syndrome risk >1:360); they were offered amniocentesis, which confirmed prenatally that each patient had a fetus with Down's syndrome. The remaining 26 pregnancies had "normal" maternal serum AFP levels but resulted in a Down's syndrome infant at delivery. This may represent an underascertainment of Down's syndrome pregnancies that are undetected by maternal serum AFP screening; 50 to 60 such pregnancies are expected.8

The 51 singleton Down's syndrome pregnancies studied constituted the case group. The control group consisted of 3239 randomly selected previously screened women with documented known normal pregnancy outcomes. Data from both groups were abstracted from the Baylor Maternal Serum Alpha-Fetoprotein Screening Program computer files.

To examine the effect of maternal serum AFP on Down's syndrome risk, cutoff points of <0.8 and ≥0.8 multiples of the median were selected to maximize specificity and sensitivity. To evaluate the modifying effect of gestational age on the association between maternal serum AFP and Down's syndrome, we stratified the maternal serum AFP data by gestational age in three categories: 14 to <16.5 weeks, 16.5 to <17.5 weeks, and 17.5 to 21.5 weeks. Although we originally stratified the data into narrower time windows, we found

that the effects were highly consistent within the three larger strata, which made it possible to gain precision (by collapsing the strata) with no loss in validity. We computed standard odds ratios and 95% confidence intervals (logit transformation) and applied the Breslow-Day test for homogeneity across strata (SAS version 6.04 PROC FREQ; SAS Institute, Inc., Carey, N.C.).

The data also were entered into a multiple logistic regression model (SAS version 6.04 PROC LOGISTIC) to adjust for the possible confounding effects of maternal age and changes in the maternal serum AFP assay method over time. The maternal age and assay-time variables were entered into the model as continuous variables. An interaction term was created as the cross product of the categoric variables gestational age and maternal serum AFP.

Results

Table I presents the mean maternal serum AFP levels (in multiples of the median) and standard deviations for cases and controls. In both groups the means are lower in the middle gestational age group (16.5 to 17.5 weeks). Between the first and second gestational age intervals, the mean multiples of the median decreases more in cases than in controls. Between the second and third gestational age intervals, the mean multiples of the median increases more in cases than in controls.

Table II shows the fourfold tables stratified by gestational age and gives the corresponding tests for association. Although the odds ratio (7.25) for the middle interval (16.5 to 17.5 weeks) differs considerably from the other two estimates (3.21 and 2.32, respectively), the difference did not achieve statistical significance in the Breslow-Day test for homogeneity. However, the Breslow-Day method tests for differences in the odds ratios on a multiplicative rather than additive scale.

When the data were entered into the multiple logistic regression model to adjust for the potential confounding effects of maternal age and assay-time, the odds ratios (mean and 95% confidence interval) decreased slightly: 2.66 (1.01 to 6.97), 5.76 (1.25 to 26.51), and

1.16 (0.38 to 3.56) for the three respective gestational age intervals. However, when we included maternal age, assay-time, and the interaction term (GA*MSAFP) in the logistic model, the coefficient for the interaction term approached significance (p = 0.148), which suggests a differential effect across gestational age.

Comment

These retrospective case-control data suggest that serum levels of AFP are most predictive of Down's syndrome between 16.5 and 17.5 weeks and that these levels become less predictive with decreasing or increasing gestational age. The interaction between gestational age and AFP is striking, especially for low AFP levels (Table I). Because our numbers are small and we may have underascertained Down's syndrome pregnancies with normal maternal serum AFP levels, our findings must be verified by a larger data set.

Since we presented our preliminary data,5 Waller et al.9 have analyzed data from the California Maternal Serum Alpha-Fetoprotein Screening Program. They found that the Down's syndrome pregnancies with the lowest maternal serum AFP values occurred between 16 and 17 weeks' gestation. Previous data from Wald and Cuckle¹⁰ suggest a trend toward increasing median maternal serum AFP levels in Down's syndrome pregnancies after 19 weeks' gestation.

The effect of gestational age on the efficiency of maternal serum AFP screening has previously been observed for open neural tube defects.11 The detection rate of open spina bifida by elevated maternal serum AFP levels is greater at 16 to 18 weeks' gestation (88% detection) than from 19 to 21 weeks' gestation (54% detection).

If our findings are confirmed, there are several implications: (1) Down's syndrome screening by maternal serum AFP is best done at 16 to 18 weeks' gestation rather than at earlier or later gestational ages, which may be another reason that some Down's syndrome pregnancies are undetected by maternal serum AFP screening.8 (2) The practice of reevaluating low maternal serum AFP levels should be discouraged, especially after 18 weeks. (3) Screening programs may need to take gestational age into account for predicting the risk of Down's syndrome. (4) These findings also may effect predictive values of combined screening that uses maternal serum AFP with human chorionic gonadotropin and unconjugated estriol.12

We thank the numerous obstetricians who provided us with follow-up information on their patients. We also thank Charles Contant, PhD, for additional statistical consultation and Sylvia Perez and R. Lillian Tanagho for manuscript preparation.

Twin gestation: Influence of placentation on fetal growth

Gabriella Pridjian, MD, Clark E. Nugent, MD, and Mason Barr, Jr., MD Ann Arbor, Michigan

To study fetal growth in twin gestation, morphometric autopsy data of 52 midgestation twin pairs who were stillborn or who died \leq 24 hours after birth were analyzed. Twins were divided into three groups: (1) monozygotic: diamniotic, monochorionic placenta (n=18); (2) dizygotic: diamniotic, dichorionic placenta, unlike sex (n=12); (3) like-sex: placenta diamniotic, dichorionic in 63.6%, unknown in 36.4% (n=22). The monozygotic group had a significantly higher rate of growth discordance, which was defined as a \geq 20% difference in body weight (monozygotic 72.2%, dizygotic 16.7%, like-sex 0%), and polyhydramnios (monozygotic 50%, dizygotic 0%, like-sex 9.1%). Organ weight z scores for body weight and brain weight standards were calculated for the smaller and larger of each twin pair. In the monozygotic group highly significant z scores were obtained for brain weight in the smaller twin (z=2.71, p=0.003, body weight standards) and heart weight in the larger twin (body weight standards, z=3.87, p<0.001; brain weight standards, z=3.64, p<0.001). We conclude that monozygotic twins with diamniotic, monochorionic placentation have a high degree of brain-sparing growth restriction in the smaller twin and cardiac hyperplasia in the larger twin, most likely caused by hemodynamic inequalities. (AM J OBSTET GYNECOL 1991;165:1394-401.)

Key words: Twin gestation, fetal growth, growth discordance, cardiac hyperplasia, intrauterine growth retardation, twin transfusion syndrome

The factors that determine fetal growth are numerous and affect the common pathway of delivery of nutrients and oxygen to the fetus. In singleton gestation these factors include the nutritional state of the mother, blood flow to the uterus, placental size, and placental transport capabilities. Additionally, intrinsic fetal genetic factors may influence fetal processing of delivered nutrients.

In multiple gestation additional factors influence fetal growth. Fetuses may merely be cohabitants of the uterus with separate placentas and fetal circulations, or they may share placentally delivered fuels via vascular connections between fetal circulations. The high degree of twin body weight discordance in monochorionic twins¹ suggests that shared fetal circulations may influence fetal growth. Clinically, inequality of shared fetal circulations is responsible for twin transfusion syndrome, which results in high fetal morbidity and mortality.

Our goal in this study was to assess the influence of vascular connections on fetal growth in twin gestation. This information might help explain the poorly understood phenomenon of twin transfusion syndrome.

Material and methods

Autopsy records of midgestation twin pairs either delivered at or referred for examination by the University of Michigan from 1974 to 1990 were reviewed. Excluded from review were pairs of twins with chromosomal abnormalities or major malformations in one or both fetuses. Twin pairs in which fetuses were macerated or died >24 hours after birth were also excluded to avoid inaccurate organ weights caused by autolytic degeneration or iatrogenic events in the nursery.

Twins were divided into three groups on the basis of placentation and fetal sex: (1) monozygotic: diamniotic, monochorionic placenta, like-sex; (2) dizygotic: diamniotic, dichorionic placenta, unlike sex; and (3) like-sex: diamniotic, dichorionic placenta or placental evaluation unavailable.

The total body weight and individual weights for the brain, spleen, thymus, thyroid, adrenal gland, kidney, heart, lung, and liver were measured and analyzed for each group. Crown-heel, crown-rump, arm, leg, and foot lengths, and head circumference were also studied. The intertwin difference in body weight for each twin pair was calculated as the weight difference between the heavier and lighter twin divided by the weight of the heavier twin.

Visceral and somatic measurements in each group were compared by calculation of the z statistic according to the following formula: z = Observed - Expected/SD of expected. The expected measurement and its SD were determined from a normal singleton reference population (n = 727, body weight 50 to 1100 gm) established at the University of Michigan. This

singleton reference population was used because the gestational age of all of the twin pairs studied was <27 weeks, and twin growth only begins to lag significantly behind singleton growth at >29 weeks.2.3 z Score calculations for visceral weights were performed for both body and brain weight standards; z scores for somatic measurements were done for body weight standards. Additional statistical analysis was performed with the two-tailed Student t test and the Fisher exact test. Linear regressions were tested for statistical significance by analysis of variance.

Results

Fifty-two twin pairs were suitable for study. Eighteen pairs had diamniotic, monochorionic placentas and made up the monozygotic group. Twelve pairs had diamniotic, dichorionic placentas and were of unlike sex; they were thus placed in the dizygotic group. The like-sex group consisted of 14 like-sex twin pairs with diamniotic, dichorionic placentas and eight like-sex pairs with unknown placental configuration that may have contained monozygotic twins with diamniotic, dichorionic placentation, dizygotic twins, and even monochorionic, monozygotic twins whose placental configuration was unavailable to us.

Antenatal complications leading to preterm delivery were similar in all three groups (Table I). The major reasons for delivery of these midtrimester twin pairs were premature labor or preterm rupture of membranes with subsequent spontaneous labor or induction. One twin pair in the monozygotic group was from a patient who chose to terminate the pregnancy because of the acute onset of severe polyhydramnios. An antenatal or intrapartum diagnosis of polyhydramnios was made significantly more often in the monozygotic group. Nine (50%) cases in that group had overt polyhydramnios; in three additional cases increased amniotic fluid was noted on ultrasonographic examination (total of 12 polyhydramnios cases, 66.7%). No twin pair in the dizygotic group and only two pairs in the likesex group had polyhydramnios.

The gestational age and mean body weight of all twins in the study groups were comparable (Table II); however, the mean body weight of the smaller and larger twins within the highly discordant monozygotic group differed by 137 gm. Among the three groups, mean intertwin difference in body weight was significantly greater in the monozygotic group (27.3%) than in the dizygotic group (13.4%, p = 0.004) and in the like-sex group (8.3%, p < 0.001). Expressed differ1396 Pridjian, Nugent, and Barr

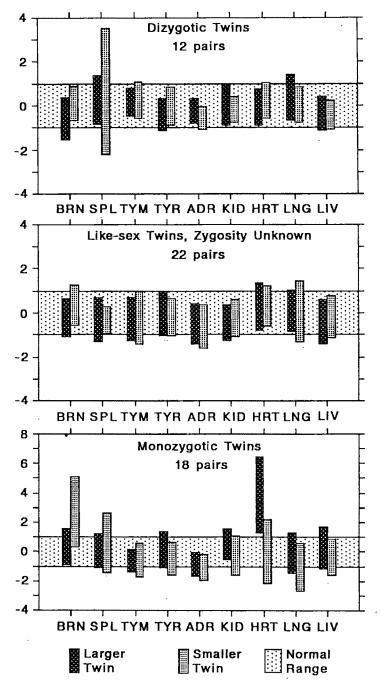

Fig. 1. z Scores (mean \pm SD) of organ weights (calculated for body weight standards) of the larger and smaller twin of each group. Organs studied were brain (BRN), spleen (SPL), thymus (TYM), thyroid (TYR), adrenal gland (ADR), kidney (KID), heart (HRT), lung (LNG), and liver (LIV). Weights of paired organs are combined. Significant mean z scores were found only for brain weight of smaller twins of monozygotic group (z=2.71, p=0.003) and in heart weight of larger twins of monozygotic group (z=3.87, p<0.001).

ently, 72.2% of the monozygotic twin pairs had a body weight discordance of >20%, which was significantly higher than the discordance rate in the dizygotic (16.7%) and like-sex (0%) groups.

The monozygotic (monochorionic) group had high degrees of both body and individual organ weight dis-

cordance. The most dramatic finding was an increased heart size in the larger twins of the monozygotic group. The heart weights of the larger twins were an average of 3.87 SD (p < 0.001) above the normal expected heart weight for body weight (Fig. 1, lower panel), and 3.64 SD (p < 0.001) above the normal expected heart weight

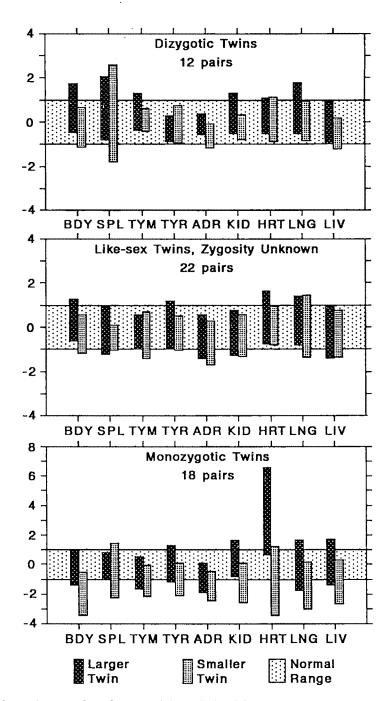

Fig. 2. z Scores (mean ± SD) of organ weights (calculated for brain weight standards) of the larger and smaller twin of each group. Organs studied were brain (BRN), spleen (SPL), thymus (TYM), thyroid (TYR), adrenal gland (ADR), kidney (KID), heart (HRT), lung (LNG), and liver (LIV). Weights of paired organs are combined. Significant mean z scores were found only for body weight in smaller twins of monozygotic group (z = -1.98, p = 0.024) and heart weight in larger twins of monozygotic group (z = 3.64, p < 0.001).

for brain weight (Fig. 2, lower panel). Additionally, the smaller twins had remarkably heavier brains for body weight. The brain weight of the smaller twins was an average of 2.71 SD (p = 0.003) above the expected brain weight for body weight (Fig. 1, lower panel). Conversely, the smaller twins of the monozygotic group had

lighter body weight for brain weight (z = -1.98,p = 0.024; Fig. 2, lower panel).

Individual organs in the smaller twins of the monozygotic group were also somewhat undergrown. Mean z scores for thymus, thyroid, adrenal, kidney, heart, lung, and liver in the smaller twins were appropriate

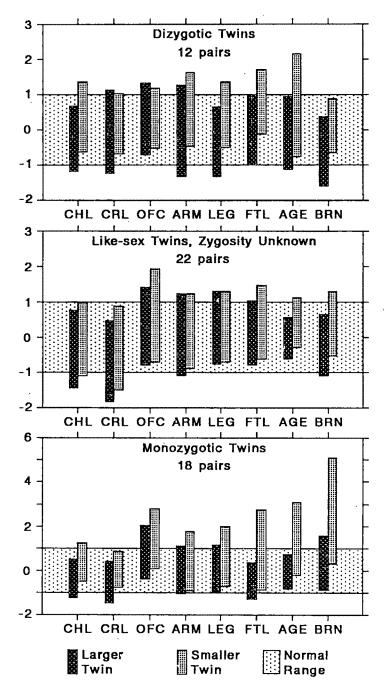

Fig. 3. z Scores (mean ± SD) of somatic measurements of the larger and smaller twin of each group studied. Measurements performed included crown-heel length (CHL), crown-rump length (CRL), head circumference (OFC), and arm length (ARM), leg length (LEG), foot lengths (FTL), gestational age (AGE), and brain weight (BRN).

for their body weight (Fig. 1, lower panel) but were modestly decreased for their brain weight (all z scores at least <-1.00, brain weight standards, Fig. 2, lower panel).

Mean z scores for individual somatic measurements of the smaller twins of the monozygotic group were within normal range for their lighter body weight (Fig. 3, lower panel) except for head circumference. A modestly high mean z score for head circumference in these smaller twins (z = 1.44, p = 0.075) again suggested brain sparing in this group.

Twin pairs that were not monochorionic (dizygotic and like-sex groups) had normal growth. In both the dizygotic and like-sex groups, the mean weights of all organs for both body and brain weight standards and mean somatic measurements for body weight standards were within the normal range.

Further examination of individual twin pairs of the

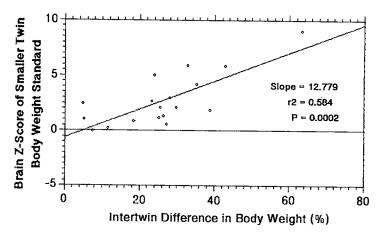

Fig. 4. Correlation of intertwin difference in body weight of individual twin pairs of monozygotic group with degree of brain-sparing growth restriction in smaller twin (graphed as brain z score, body weight standard).

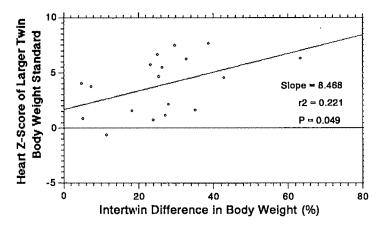

Fig. 5. Correlation of intertwin difference in body weight of individual twin pairs of the monozygotic group with degree of cardiac hyperplasia in larger twin (graphed as heart z score, body weight standard).

monozygotic group revealed that the percentage of body weight discordance between the twins of a pair correlated strongly ($R^2 = 0.584$, p < 0.001) with the degree of brain sparing in the smaller twin (Fig. 4), indicating that asymmetric intrauterine growth retardation of the smaller twin was a feature of this group. The correlation between percentage of body-weight discordance within twin pairs of the monozygotic group and the degree of cardiac hyperplasia in the larger twin (Fig. 5) was not as strong ($R^2 = 0.221$, p = 0.049). Notably, in the monozygotic group the larger twins of two twin pairs with minimal body weight discordance had elevated heart weights (z = 3.73 and 3.97). Correlations in the dizygotic and like-sex groups between degree of body weight discordance and z scores for brain weight or heart weight did not approach statistical significance.

A clinical diagnosis of twin transfusion syndrome was made in 6 of 18 twin pairs of the monochorionic group (33.4%) when growth discordance and acute polyhydramnios were noted. After pathologic evaluation, twin transfusion syndrome was suspected in 15 of 18 cases (83.3%) because of growth discordance, polyhydramnios, and a large heart for body weight in the larger twin. Fetal hematocrit levels were not available.

Comment

Numerous factors affect fetal growth. In this study we evaluated the growth characteristics of prematurely delivered midgestation twins, one group (monozygotic) of whom had placental vascular anastomosis. If carefully inspected, vascular anastomosis connecting fetal circulations can be found in nearly all monochorionic placentas.4 Dichorionic, diamniotic placentation that is either monozygotic or dizygotic in origin is only very rarely associated with fetal vascular communications.5 Thus we considered growth differences in the monozygotic group to be primarily influenced by inequality of fetal blood flow because genetic factors determining growth of twin pairs in this group should be identical. Intertwin differences of growth in the dizygotic group could be attributed to genetic factors, especially those

differences associated with fetal sex, because all twin pairs in this group were of unlike sex. Because the like-sex group was probably heterogeneous in zygosity and placentation, multiple factors could have affected growth in these twins. Surprisingly, this heterogeneous group of like-sex twin pairs had minimal intertwin growth variations. Finally, all three groups of twins were subject to varied, undefined maternal factors that influence growth.

In our study the twin pairs of the monozygotic group had a high degree of intertwin growth discordance and polyhydramnios when compared with the dizygotic or like-sex groups, a finding that agrees with the work of others. ^{1, 6} A large fraction of these twin pairs thus displayed indirect evidence of twin transfusion syndrome. Grennert et al. ⁷ used ultrasonographic measurements to calculate fetal weights and found a greater absolute intrapair weight difference in dizygotic twins. The twin pairs studied were all >28 weeks' gestation and delivered near term. The monozygotic group also contained twins with diamniotic, dichorionic placentation, diluting the differential growth effects of vascular anastomosis.

The proportion of monochorionic twins in our study (35%) was greater than would be expected if compared with the incidence of monochorionic twins in the population (20%).8 Our overrepresentation of monochorionic twins may be caused by either an increased midgestation loss of this type of twin or an increased referral of this type of twin for detailed evaluation.

In body weight-discordant pairs of the monozygotic group, the larger twin was of normal weight and the smaller twin was underweight. Others have reported similar findings by using ultrasonographic estimations of fetal weight in twins carried to near term.9 In our study the smaller twin of the monozygotic group displayed brain-sparing growth restriction. The degree of brain sparing in these twins correlated with the percentage of intertwin body weight difference, indicating that restricted growth of the smaller twin and not overgrowth of the larger twin is responsible for body weight discordance. Four of the body weight-discordant twin pairs of the monozygotic group had brain weight discordance >20% (data not shown), suggesting that some of these fetuses were subject not only to brain-sparing growth restriction but perhaps also to factors that influence growth very early in gestation and result in decreased brain cell number.10

In the smaller twins of the monozygotic group, the majority of the remaining internal organs studied were also undergrown. Except for head circumference, somatic measurements of these twins also corresponded to their lighter weight.

The most dramatic finding in this study was the high degree of cardiac hyperplasia¹¹ in the larger twin of the monozygotic group. In this group an increased heart weight in the larger twin was found in eight of nine twin pairs with overt polyhydramnios. However, the degree of heart weight increase correlated weakly with the degree of body weight discordance. The larger twins of two twin pairs with minimal body weight discordance were found to have large hearts and polyhydramnios; these findings suggest that hemodynamic imbalance between twins may precipitate cardiac hyperplasia before a major growth disturbance is evident.

We found that monochorionic twin pairs have a high degree of brain-sparing growth restriction in the smaller twin and cardiac hyperplasia in the larger twin. We support the theory that twin transfusion syndrome is a condition that begins early in embryonic vascular development. Benirschke12 described the youngest example, a pair of aborted twin embryos measuring 7 and 8 cm (10 weeks' gestation) in which the heart size of the donor twin was half that of the recipient. Further, we suggest that intertwin vascular distribution established early in the embryonic period may control intertwin placental mass distribution. Inequality in placental mass distribution may have an early direct effect on fetal growth, causing significant growth restriction in one fetus. Alternatively, intertwin vascular connections may produce chronic twin transfusion syndrome, in which the larger twin responds with cardiac hyperplasia. Cardiac hyperplasia may be compensatory and certain sets of monochorionic twins may withstand the vascular inequalities throughout gestation (subclinical twin transfusion syndrome). In others, the pumping capabilities of the enlarged heart are exceeded and cardiac failure occurs, producing a more acute picture of twin transfusion syndrome. It is tempting to speculate that when the heart enlarges and fails, delicate pressure-flow characteristics in the placental vasculature are disrupted, exacerbating shunting to the recipient twin.

It is not surprising that the appropriate diagnostic criteria used to detect twin transfusion syndrome in the newborn period are still debated¹³ because the mechanisms leading to acute twin transfusion syndrome are still unclear. Cardiac hyperplasia may initially be a physiologic response to increased circulatory volume, but beyond a certain degree it may play a role in the development of the syndrome. In women with ultrasonographically diagnosed monochorionic twins,¹⁴ the usefulness of echocardiography for the antenatal diagnosis of twin transfusion syndrome should be studied. Longitudinally assessed echocardiographic parameters in monochorionic twins may shed light on the natural history of the syndrome and may be predictive of adverse outcomes in these twin pairs.

Myocardial necrosis in a newborn after long-term maternal subcutaneous terbutaline infusion for suppression of preterm labor

Scott E. Fletcher, MD,^a Derek A. Fyfe, MD, PhD,^{a,c} Christopher L. Case, MD,^a Henry B. Wiles, MD,^a Jane K. Upshur, MD,^b and Roger B. Newman, MD^c

Charleston, South Carolina

We report a case of myocardial necrosis in a newborn after treatment of the mother with long-term subcutaneous terbutaline. No such serious side effects in the fetus have previously been reported. We speculate that this myocardial damage was due to β-sympathomimetic therapy. (AM J OBSTET GYNECOL 1991;165:1401-4.)

Key words: Cardiomyopathy, infant, subcutaneous, β-sympathomimetics

β-Sympathomimetic agents have become accepted as therapy for the suppression of preterm labor. Continuous subcutaneous terbutaline hydrochloride has recently been administered for long-term tocolysis.¹ Long-term (9 weeks) maternal subcutaneous terbutaline infusion has resulted in no maternal or fetal complications.¹ We report a case of an infant in whom dilated cardiomyopathy and myocardial necrosis occurred after long-term, low-dose subcutaneous terbutaline infusion.

Case report

A male infant was born at 37 weeks' gestation to a 22-year-old, gravida 2, para 1 woman. The pregnancy was complicated by gestational diabetes and preterm labor. At 25 weeks' gestation continuous, subcutaneous terbutaline infusion (0.5 mg/hr) for treatment of preterm labor was begun. During the final 2 weeks of pregnancy, additional 0.3 mg bolus infusions were added each hour to the baseline infusion.

At birth the baby weighed 2850 gm and appeared normal. However, tachypnea of 80 to 100 breaths/min developed in the infant. No evidence of infection was detected. Chest radiography showed mild cardiomegaly with increased pulmonary vascularity. Tachypnea persisted, and on the fourth day of life a cardiologic evaluation was performed. The heart rate was 145 beats/min, respirations were 60 breaths/min, and blood pressure was 81/58 mm Hg. There was a grade 2/6 systolic murmur at the lower left sternal border

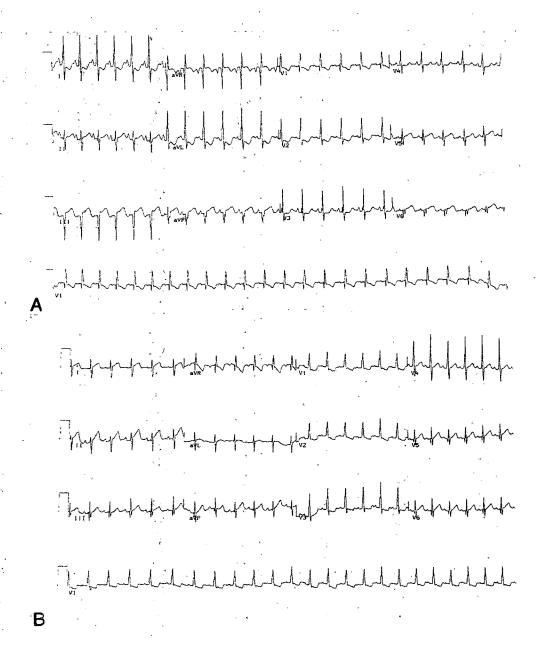

Fig. 1. A, Initial electrocardiogram showing abnormally deep Q waves in inferior leads with ST segment elevation. Reciprocal ST segment depression is seen anteriorly. B, Note small residual Q waves in inferior leads without ST segment changes. This electrocardiogram was done 1 month after initial presentation.

with normal pulses; hepatosplenomegaly was not present. Electrocardiogram showed deep Q waves in aVR, aVF, and III with ST segment elevation (Fig. 1, A). Echocardiogram showed decreased left ventricular shortening fraction of 12% (normal, 32% to 40%) and an enlarged end-diastolic dimension of 2.5 cm (upper normal, 2.0 cm) (Fig. 2, A). Tricuspid regurgitation was present.

Treatment for congestive heart failure was initiated with digoxin 10 mcg/kg/day, furosemide 2 mg/kg/day, and captopril 2 mg/kg/day. The baby improved clin-

ically, and the respiratory rate normalized by the seventh day of life.

Infectious and metabolic causes of cardiomyopathy were excluded. Cardiac catheterization on day 9 showed normal coronary arteries. Right ventricular biopsy showed marked myocardial fiber degeneration and focal bizarre nuclear dysmorphism (Fig. 3), which were independently interpreted as being consistent with myocardial injury caused by catecholamine excess.

The infant recovered rapidly and went home on day 12. At 1 month of age no abnormal findings were pres-

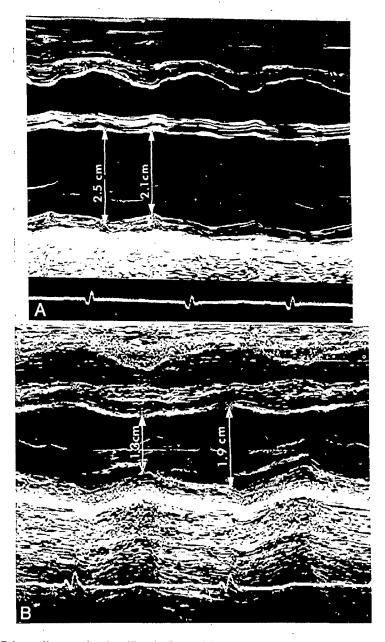

Fig. 2. A, Echocardiogram showing dilated left ventricle with markedly decreased shortening fraction of 12%, compared with B, which shows return of left ventricle to normal dimensions and systolic function.

ent. The electrocardiogram showed a normal sinus rhythm with small residual Q waves in the inferior leads and resolution of ST segment changes (Fig. 1, B). Echocardiogram showed normal left ventricular dimensions and a normal shortening fraction of 32% (Fig. 2, B).

Comment

Subcutaneous β-sympathomimetic infusion is a relatively new form of tocolytic therapy. Initial clinical trials have suggested that subcutaneous infusion has a longer duration of tocolysis than does intermittent high-dose oral therapy. All "β2-selective" agents, however, have significant β-sympathomimetic cardiostimulatory side effects.

Bohm and Adler² performed autopsies on the hearts of 25 infants whose mothers had received intravenous or oral "β₂-specific" sympathomimetics for tocolysis for up to 12 weeks. Deaths were attributed to complications of prematurity. Histologic examination showed myocardial necrosis, fatty degeneration, and nuclear polyploidization.2

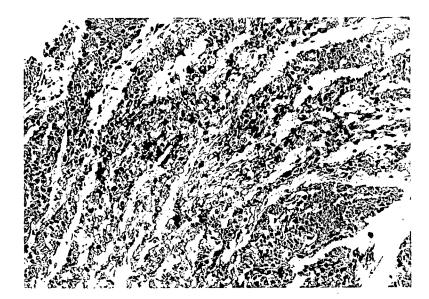

Fig. 3. Severe vascular degeneration of myofibers with early clumping of sarcoplasm. Few enlarged myofiber nuclei are seen in subendomyocardium. (Hematoxylin and eosin. Original magnification \times 200.)

Various forms of myocardial injury by β -sympathomimetics have been proposed, such as excessive catecholamine cardiac stimulation, diminished circulatory pressure, increased metabolic demand, and calcium influx into the myoplasm of cardiac cells.

Although a causative relationship between cardiomyopathy and β -adrenergic receptor therapy cannot be proved in this case, circumstantial evidence includes prolonged exposure to β -adrenergic receptor agonist therapy, poor ventricular contractility with no structural anomaly, and histologic demonstration of myocardial necrosis identical to that described with catecholamine excess.

Delivery systems for continuous long-term β -adrenergic stimulation must be carefully evaluated for ad-

verse fetal receptor effects. Continuous low-dose terbutaline infusion may maximize tocolytic effectiveness by minimizing β -adrenergic receptor down regulation. However, such receptor down regulation may be protective to the fetal myocardium. The fetal cardiac effects of continuous long-term β -adrenergic receptor tocolysis need further evaluation.

Vasopressin pack for treatment of bleeding after myoma resection

Duane E. Townsend, MD

Sacramento, California

In 17 women with refractory bleeding after myoma resection a dilute vasopressin pack was applied. Twenty units of vasopressin was diluted with 30 ml normal saline solution. A 1-inch new gauze pack was soaked in the dilute vasopressin and packed into the uteri of patients with bleeding from the beds of resected submucous myomas. The pack was left in place for no more than an hour. In none of the cases was there bleeding after the removal of the pack nor were there any side effects that could be attributed to the vasopressin. (AM J OBSTET GYNECOL 1991;165:1405-7.)

Key words: Vasopressin pack, bleeding

Heavy bleeding from the bed of either a completely or a partially resected submucous myoma during or after operative hysteroscopy can at times be difficult to control. One of the more common methods for managing this problem is the insertion of an intrauterine balloon or a Foley catheter with a 30 ml balloon and then inflating the balloon with as much fluid as possible to tamponade the bleeding. The catheter is left in place for as short a time as 2 to 3 hours or as long as 24 hours.1-3 When this technique was used in several patients, the degree and duration of pain were impressive. Because of the stimulatory effects of vasopressin on the smooth muscle of the uterus and blood vessels and the known benefit of compression on bleeding, a dilute vasopressin-soaked pack was placed in the uterus to assess the utility of this method to control bleeding in a series of patients who had undergone partial or complete resection of submucous myomas.

Material and methods

The study population comprised 17 of 150 women between the ages of 25 and 50. This group of patients had surgery between February 1988 and July 1990. Of this group, five were Nulliparous and the remaining had from one to four term pregnancies. All complained of heavy menstrual bleeding with two thirds requiring oral iron for maintenance of hemoglobin between 8 and 10 gm. In the remaining patients the hemoglobin ranged between 10 and 12 gm with oral iron. In all cases the menstrual bleeding interfered with normal activities. None of the patients had evidence of any

coagulation disorders or evidence of thyroid dysfunction. Hysterectomy was strongly suggested in all of the women in spite of the fact that several desired children. All patients had requested alternative means of therapy to control the bleeding.

More than half of the patients had had a curettage performed within 12 months of the operative procedure, and in none of the cases was the submucous myoma detected nor was the bleeding controlled by curettage. Within 6 months of the operation all patients had received some type of hormone therapy, either oral contraceptives or various progestins, without benefit.

All patients underwent office video hysteroscopy with dilute dextran 70 (Hyskon, Pharmacia Laboratories, Piscataway, N.J.) as the distending medium to establish the diagnosis. Biopsies of suspicious areas were performed, and the specimens were used to establish ovulation.

In five patients the objective was to resect the myoma only to control the bleeding, and in four of these fertility was the major issue. In the remaining 12 patients the plan was to resect the myoma and then perform roller-ball endometrial ablation to markedly reduce or stop the menstrual flow.

All patients received some type of preoperative medication to suppress ovulation and thin the uterine lining. In seven patients danazol (Danocrine, Winthrop Pharmaceuticals, New York), 800 mg a day for 6 weeks, was used; in three patients medroxyprogesterone acetate (Depo-Provera, Upjohn Co., Kalamazoo), 400 mg 4 weeks before the planned surgery, was given; and in the remaining seven patients medroxyprogesterone (Provera, Upjohn Co.), 10 mg twice a day for 6 weeks, was used.

A 2 to 3 mm laminaria tent was placed into the cervix and through the internal cervical os 24 hours before surgery in all patients, and all were started on a regimen of doxycycline hyclate (Vibramycin, Pfizer, Parsippany,

6/1/30053

N.J.), 100 mg twice a day. All were given a prescription for hydrocodone bitartrate (Vicodin, Knoll Pharmaceuticals, Whippany, N.J.) for preoperative and postoperative pain control. On the day of surgery the patients were given a general anesthetic, the laminaria tent was removed, and the patients were prepped and draped for the procedure. A 3% sorbitol solution was used as the irrigating medium, and an Olympus 27 Fr. dual-channel irrigating resectoscope (Olympus Corp., Lake Success, N.Y.) was used in performing the procedures. In those patients in whom resection only was performed, a wire loop electrode was used with a cutting current of 120 W blend 2. In those individuals who were undergoing both resection and ablation, a rollerball electrode was attached to the instrument after resection of the myoma, and the endometrium was coagulated at 100 W. At the end of the operative procedure, the irrigating fluid was stopped, and the resected base was examined. If brisk bleeding was observed, attempts were made to control the bleeding by coagulating the base with either a wire loop or rollerball electrode. In 17 cases the bleeding was not sufficiently controlled as determined by bleeding that filled the vagina over a 30-second time period. Packing was performed with a 1-inch new gauze cotton packing that had been soaked with a dilute vasopressin solution, i.e., 20 U vasopressin diluted with 30 ml injectable normal saline solution. The moistened gauze was firmly packed into the uterine cavity with either a packing forceps or long smooth finger forceps. As much packing as possible that could be firmly placed in the cavity was used. This was performed quite easily because in all patients the cervix had been softened and dilated with the laminaria tent. In one patient the entire pack (60 inches) was placed in the cavity, but in most instances from one fourth to one half of the pack was used. The patients were awakened from anesthesia and taken to the recovery room. Vital signs were observed every 15 minutes for the next 2 hours. The pack was removed within 1 hour after surgery, and the patients were ambulated. If bleeding was insignificant, the patient was discharged within 1 hour. All patients were seen at 6 weeks and 6 months after surgery.

In the five patients who were undergoing resection only, the entire tumor was resected in four cases and in the remaining instance it was felt that at least two thirds of tumor had been removed. In those patients who were undergoing resection and ablation, the myomas were resected completely in six and in the remaining at least two thirds or more before ablation.

Results

In all cases the dilute vasopressin pack appeared to be successful in controlling bleeding after the operative procedure. In none of the patients was there any significant bleeding through the pack for the first hour after surgery. None of the patients had any significant degree of bleeding, i.e., no more than one soaked pad per hour after the pack was removed. In fact, in all patients there was only light staining of the perineal pad.

After discharge none of the patients complained of any significant bleeding during the immediate post-operative period. At 6 weeks and 6 months they were carefully queried as to the degree of bleeding, and in none of the cases was it significant. In those patients who had only resection of a myoma, the menses returned to normal, according to the patients. In two patients, pregnancy was achieved within 6 months after surgery, and one has been delivered of a healthy term infant; the remaining patient is still pregnant. In those individuals who had had resection and ablation, all had no bleeding or only spotting at 6 weeks and 6 months after therapy.

All of the patients complained of some degree of pain in the immediate postoperative period, but narcotics were required to relieve the pain only in half. Once the pack was removed, none noted further pain. Although all patients had received prescriptions for analgesics for the postoperative period, only two used the medication, for 1 day only.

The irrigating fluid that was used during surgery varied between 8000 and 56,000 ml, and in each case a fluid balance was within accepted guidelines, i.e., fluid output versus fluid input difference of ≤1000 ml.⁴

All patients had careful monitoring of blood pressure and vital signs while they were in the recovery room, and in none of the cases was there any evidence of tachycardia, hypertension, or hypotension.

Comment

The results of this study indicate that a dilute vasopressin pack is a safe and effective way to control bleeding from the bed of a resected submucous myoma that cannot be controlled with cauterization. Because of reports of problems with injecting even dilute vasopressin,⁵ it was decided not to inject the tissues directly but to deliver the vasopressin to the tissues by a packing technique. The duration the pack was left in the uterus was arbitrary. Because the patients wanted to go home, it was initially decided that the pack would be removed within an hour in the first six patients. Because they did so well, this practice was continued and has been continued to date. It has not been necessary to repack because of bleeding.

Compression for control of bleeding has been used for centuries. Intrauterine packing for postabortion and postpartum bleeding is controversial. Packing was used in these cases both to deliver the vasopressin into the uterus and to apply topical compression. Whether a pack alone or vasopressin alone would be just as effective remains to be determined and is the subject of additional studies.

Vasopressin is primarly an antidiuretic hormone. The drug also causes active contraction of virtually all smooth muscles in the body, including blood vessels, intestines, and uterus. Injected vasopressin has been used to control bleeding with operative hysteroscopy.² Because of reports of death with injected vasopressin,⁵ it was elected not to inject the tissue in these patients but rather to deliver the vasopressin by pack. The mechanism of action in this study is probably twofold. The pack provides control of bleeding by compression, but when the packing material contains vasopressin, the uterus undergoes further contraction that adds to the benefits of the pack. A tertiary effect may be in the vessels of the uterus.

None of the patients had exhibited any sign of infection, but all had been placed on a regimen of antibiotics before surgery. Moreover, none of the patients had any evidence of the cardiovascular changes that are reported with vasopressin.

It appears, from this evaluation in 17 patients who underwent partial or complete resection of submucous

myomas with refractory bleeding, that a dilute vasopressin pack is an effective and safe way to control such bleeding. The pack can be removed within a short time, thereby permitting an early discharge. It is urged, however, that when patients undergo operative hysteroscopic procedures they should remain relatively inactive for about 3 weeks, as we have known of bleeding in some patients who exercised vigorously during the first 21 days after surgery.⁴

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of \$61.00 for domestic, \$88.27 for Canada, and \$84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. Payment must accompany all orders. Contact Mosby—Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Severe preeclampsia in the second trimester: Recurrence risk and long-term prognosis

Baha M. Sibai, MD, Brian Mercer, MD, and Cem Sarinoglu, MD Memphis, Tennessee

A total of 125 women with severe preeclampsia that developed in the second trimester underwent follow-up for an average of 5.4 years. Seventeen women had no further pregnancies and 108 had 169 subsequent pregnancies: 59 (35%) were normotensive and 110 (65%) were complicated by preeclampsia (32% of these developing in the second trimester, 32% at 28 to 36 weeks, and 36% at 37 to 40 weeks). Overall, 21% of subsequent pregnancies were complicated by severe preeclampsia in the second trimester. Forty-four patients (35%) had chronic hypertension, the highest incidence being in those with recurrent severe preeclampsia in the second trimester and the lowest in those with only normotensive subsequent pregnancies (67% vs 4%, p < 0.0001). Long-term maternal complications included two maternal deaths and two other patients with end-stage renal disease requiring dialysis. We conclude that these women are at increased risk for repeat preeclampsia, particularly in the second trimester, and are at increased risk for chronic hypertension and maternal mortality and morbidity. (AM J OBSTET GYNECOL 1991;165:1408-12.)

Key words: Preeclampsia, second trimester, recurrence, chronic hypertension

Severe preeclampsia developing in the second trimester is a rare complication of pregnancy. These pregnancies are usually associated with increased perinatal mortality and morbidity. ¹⁻³ In addition, such pregnancies are associated with significant maternal morbidity: pulmonary edema, disseminated intravascular coagulopathy, hypertensive encephalopathy, convulsions, and acute renal failure. ^{1, 2, 4}

Counseling of the patient whose pregnancy is complicated by severe preeclampsia during the second trimester is a difficult task for the obstetrician, because there are no data regarding risk of recurrence and long-term maternal outcome. We previously reported that women having severe preeclampsia-eclampsia in their first pregnancy are at increased risk for having preeclampsia in subsequent pregnancies and at increased risk for chronic hypertension later in life. However, very few patients studied in that report had severe preeclampsia in the second trimester. The purpose of this study is to report subsequent pregnancy outcome and remote maternal prognosis in 125 women with severe preeclampsia that developed in the second trimester.

Material and methods

The study population consisted of 125 women who had severe preeclampsia during the second trimester

From the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Tennessee, Memphis. Received for publication December 12, 1990; revised April 1, 1991; accepted April 10, 1991.

(18 to 27 weeks' gestation). The diagnosis and management in these cases were previously described. 1,2 All patients were delivered during the index pregnancy at the E.H. Crump Women's Hospital and Perinatal Center, Memphis. Patients with preexisting diabetes mellitus, connective tissue disease, or sickle cell disease and those with inadequate medical follow-up were excluded. Inclusion criteria included adequate medical follow-up for a minimum of 2 years after delivery of the index pregnancy.

Pregnancy outcome in subsequent pregnancies was reviewed with regard to gestational age at time of delivery, incidence of preeclampsia, and perinatal outcome. Only pregnancies delivered beyond the first trimester are included in this analysis. The diagnosis of chronic hypertension was based on the presence of documented hypertension (either before index pregnancy or on follow-up) for which the patient received antihypertensive therapy. Maternal blood pressure measurements were performed with the patient in the sitting position after 5 minutes of quiet rest; the arm used was in a roughly horizontal position at heart level. The fifth (disappearance) Korotkoff sound was used to determine the diastolic blood pressure.

All patient records were carefully and extensively reviewed by B.M.S. In the majority of cases (90%) the patients were seen and followed up by B.M.S. In other cases hospital records and the records of other medical providers were accepted only if they were determined to be adequate. Maternal blood pressure recordings were obtained at 6 to 8 weeks post partum and then once every year.

Data analysis was done with the use of χ^2 and odds ratios; p < 0.05 was considered significant.

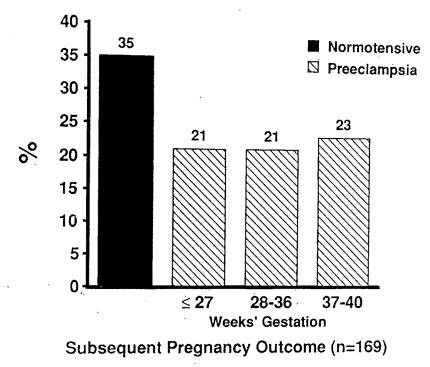

Fig. 1. Pregnancy outcome in 108 women who had subsequent pregnancies: 35% were normotensive and 65% were complicated by preeclampsia.

Results

Table I summarizes the clinical findings in the index pregnancy among the 125 women studied. The 125 women underwent follow-up for an average of 5.44 years (range, 2 to 12). Seventeen women had no further pregnancies, and 108 had 169 subsequent pregnancies (range, one to four per patient). In 59 (35%) of these pregnancies the women were normotensive, whereas 110 (65%) were complicated by preeclampsia. Of those complicated by preeclampsia, it developed in the second trimester in 35 (32%), at 28 to 36 weeks in 35 (32%), and at 37 to 40 weeks in 40 (36%). Fig. 1 summarizes the overall incidence of preeclampsia in subsequent pregnancies according to gestational age at the time of onset. Overall, 21% of subsequent pregnancies were complicated by severe preeclampsia in the second trimester.

The 169 subsequent pregnancies resulted in 170 births (one set of twins). There were 22 stillbirths and six neonatal deaths, for an overall perinatal loss of 16.5%. Eleven (6.5%) of the pregnancies were complicated by abruptio placentae, and 39 (23%) were complicated by fetal growth retardation (birth weight <10th percentile for gestational age). Table II summarizes the pregnancy outcome in subsequent pregnancies according to whether the women were normotensive or had preeclampsia. There were two perinatal deaths in the normotensive group; one was a stillbirth at 32 weeks' gestation (normal findings on autopsy), and one was a neonatal death after preterm delivery at 24 weeks' gestation due to premature rup-

ture of membranes. In addition, the majority of poor pregnancy outcomes in the preeclamptic group were in those who had repeat second-trimester preeclampsia.

A total of 44 patients had chronic hypertension; 21 of these women had chronic hypertension before the index pregnancy (one of them also had glomerulonephritis). The other 23 patients had evidence of chronic hypertension on follow-up. The average time interval from delivery to the development of hypertension in these patients was 6.1 years (range, 1 to 11).

Seven (41%) of the 17 women with no subsequent pregnancies had chronic hypertension; six of these had chronic hypertension before the index pregnancy and the other patients had chronic hypertension on follow-

up. On the other hand, 37 (34%) of the 108 with subsequent pregnancies had chronic hypertension, 15 before the index pregnancy, whereas the other 22 patients had chronic hypertension on follow-up.

A total of 93 patients without evidence of chronic hypertension before the index pregnancy had subsequent pregnancies on follow-up. Eighty-nine were normotensive, and four had persistent elevations of blood pressure 6 to 8 weeks after delivery of the index pregnancy. The latter four patients had chronic hypertension that developed after 1 to 3 years of follow-up. The remaining 89 patients who were normotensive post par-

tum had a total of 130 subsequent pregnancies. In 58 (45%) of these pregnancies the women were normotensive, whereas 72 (55%) pregnancies were complicated by preeclampsia. Among these, preeclampsia developed in the second trimester in 20 (28%), at 28 to 36 weeks in 25 (35%) and at 37 to 40 weeks in 27 (37%).

Table III describes the frequency of chronic hypertension, according to subsequent pregnancy outcome among the 108 women studied. The incidence of chronic hypertension was significantly higher in those women, who had subsequent preeclampsia than in those who were normotensive in subsequent pregnancies (43% vs 4%, p < 0.0001; odds ratio, 18.4:1). The highest incidence of chronic hypertension was in those women with recurrent severe preeclampsia in the second trimester (67%).

The data were subsequently analyzed after the 15 women who had chronic hypertension before the index pregnancy were excluded. Table IV describes the incidence of chronic hypertension diagnosed on follow-up, according to outcome in subsequent pregnancies. Again, the incidence of chronic hypertension was significantly higher in women who had subsequent pre-eclampsia as compared with those with only normotensive subsequent pregnancies (31% vs 4%, p < 0.005; odds ratio, 10.7:1). In addition, the highest incidence of chronic hypertension was among women with recurrent severe preeclampsia in the second trimester (55%).

In four patients serious maternal complications developed during the follow-up period; two of them died and two patients had end-stage renal disease necessitating dialysis. All four patients had long-standing chronic hypertension, and three of the four had the index pregnancy complicated by abruptio placentae, fetal death, disseminated intravascular coagulation, and acute renal failure. One patient had acute renal failure caused by bilateral cortical necrosis immediately after delivery of the index pregnancy. This patient had no subsequent pregnancies. The other three patients had subsequent pregnancies that were complicated by severe preeclampsia in the second trimester; one of them died of a cerebrovascular accident 5 years after

^{*}n = 36 (one set of twins).

the index pregnancy (3 months after the recurrent second-trimester preeclampsia). One patient had three consecutive pregnancies complicated by preeclampsia in the second trimester (two of which also were complicated by acute renal failure). She required dialysis 7 years after the index pregnancy and eventually died at 9 years 5 months after the first episode. In the remaining patient with preexisting glomerulonephritis end-stage renal disease developed about 21/2 years after the index pregnancy and is currently on dialysis after 5 years of follow-up.

Comment

Two recent studies revealed that women who have preeclampsia in their first pregnancy are at increased risk for having preeclampsia in subsequent pregnancies.5.6 In addition, both studies found that the risk of having preeclampsia in subsequent pregnancies is related to the time of onset of preeclampsia during the first pregnancy. However, neither of these studies described the risks for women with severe preeclampsia that develops in the second trimester.

The results of this study show that women with severe preeclampsia that develops in the second trimester are at very high risk for severe preeclampsia in subsequent pregnancies. In such women 65% of all subsequent pregnancies were complicated by preeclampsia. It is important to emphasize that 21% of all subsequent pregnancies were complicated by severe preeclampsia in the second trimester and 21% were complicated by severe preeclampsia at 28 to 36 weeks' gestation. Thus these patients should be informed of the high likelihood of severe preeclampsia and poor perinatal outcome in subsequent pregnancies. Women considering pregnancy should be instructed to seek prenatal care early in the first trimester. In addition, they should be seen more frequently, starting in the second trimester, so that the onset of hypertension can be detected as early as possible. Moreover, such patients might be good candidates for receiving low-dose aspirin during pregnancy to prevent the onset of early preeclampsia.7

Patients with severe preeclampsia that develops remote from term are at increased risk of chronic hypertension and undiagnosed underlying renal disease.5,6,8,9 Ihle et al.8 studied renal function at 6 weeks to 6 months post partum in 84 patients with severe preeclampsia that developed at 24 to 36 weeks' gestation. Maternal evaluation included a 24-hour urine study, urine microscopy, intravenous pyelography, and renal biopsy when appropriate. The authors found a high incidence of renal disease and essential chronic hypertension (90%). In two thirds of these patients the lesion was glomerulonephritis, mostly of the immunoglobulin A variety. They concluded that such women usually have underlying renal disease that should be evaluated after delivery. In contrast, Lin et al.9 reported on the pregnancy outcome and prognosis in 157 women in whom the etiology of hypertensive complications of pregnancy was determined by postpartum renal biopsies. The authors found that most of the women (62%) who were delivered before 37 weeks' gestation had the renal lesion of preeclampsia.

The results of this study show that patients having severe preeclampsia in the second trimester have a significantly high incidence of chronic hypertension. This incidence is significantly higher in those having subsequent hypertensive pregnancies. In addition, the incidence is highest in those with severe preeclampsia that again develops in the second trimester. On the other hand, patients who are normotensive in subsequent pregnancies have an extremely low incidence of chronic hypertension on follow-up (Table IV). This information may be useful for the counseling of such patients about subsequent medical follow-up.

It is important to emphasize that women having severe preeclampsia in the second trimester are at increased risk for long-term maternal morbidity or for mortality. Two of these women died; one death was due tò a cerebrovascular accident and one was a result of end-stage renal disease. In addition, end-stage renal disease necessitating dialysis developed in two other patients. All four serious complications developed in women with long-standing, preexisting chronic hypertension. Interestingly, only three of these four patients had subsequent pregnancies, and all subsequent pregnancies were complicated by severe preeclampsia in the second trimester. Thus such patients should be informed about these risks and should be counseled regarding close medical follow-up in the future.

In summary, patients with severe preeclampsia that develops in the second trimester should be considered at increased risk for severe preeclampsia in subsequent pregnancies and at increased risk for chronic hypertension. In addition, women with recurrent severe preeclampsia that develops in the second trimester are at increased risk for maternal mortality and morbidity later in life.

A case report of prostaglandin E₂ termination of pregnancy complicated by Cushing's syndrome

Monica A. Buescher, MD, Howard D. McClamrock, MD, and Eli Y. Adashi, MD Baltimore, Maryland

A case of Cushing's syndrome caused by an adrenal adenoma seen at 10 weeks' gestation is described. The pregnancy was terminated at 18 weeks' gestation, representing the first reported case of therapeutic termination of pregnancy in Cushing's syndrome with prostaglandin E₂ vaginal suppositories. (AM J OBSTET GYNECOL 1991;165:1412-3.)

Key words: Cushing's syndrome in pregnancy, hypertension in pregnancy

A case of Cushing's syndrome associated with an adrenal adenoma at 10 weeks' gestation is reported.

Case report

A 28-year-old black woman, gravida 3, para 2, was referred to University Hospital for termination of pregnancy at 13 weeks' gestation with a presumptive diagnosis of Cushing's syndrome. The patient was first admitted to a community hospital at 10 weeks' gestation for evaluation of hypertension. At this time blood pressure was 206/150 mm Hg with otherwise unremarkable findings at physical examination. She denied any history of hypertension or serious medical illness and had last been examined by a physician 7 months earlier. Menses had been regular to date. Laboratory parameters were obtained; hemoglobin value, serum electrolyte levels, serum creatinine level, creatinine clearance value, and thyroid and liver function test results were normal. One-hour glucose tolerance testing with a 50 gm load was elevated at 176 mg/dl. Twenty-four-hour urinary metanephrine levels were normal. Evaluation of the adrenal axis revealed an evening serum cortisol level of 33.1 µg/dl, 24-hour urinary free cortisol level of 1000 µg, and a 24-hour urinary 17-hydroxycorticosteroid value of 13.1 mg. These values were interpreted as normal for pregnancy. The patient was discharged after antihypertensive therapy was adequately established.

She was seen by the visiting obstetric consultant in

She was seen by the visiting obstetric consultant in the outpatient clinic at 13 weeks' gestation. The patient appeared lethargic and admitted to easy fatigability. Blood pressure was poorly controlled at 180/120 mm Hg. Physical examination was unchanged except for the presence of moon facies and purple striae over the abdomen and upper and lower extremities. The abdomen was protuberant. Presumptive diagnosis of Cushing's syndrome was made on the basis of the findings at physical examination and the previously determined adrenal studies. The patient indicated at this time her wish to terminate the pregnancy, and she was referred to the tertiary care center for continuing evaluation and pregnancy termination.

The patient was lost to follow-up until 17 weeks' gestation, at which time she was admitted to University Hospital. Biochemical evaluation revealed frank diabetes with fasting blood glucose levels of 150 to 200 mg/dl. Repeat evaluation of adrenal function confirmed the previously noted elevation: Diurnal variation of serum cortisol was abolished with a morning level of 71.8 mg/dl and an evening level of 59.6 mg/dl. Twenty-four-hour urinary free cortisol level

From the Department of Obstetrics and Gynecology, University of Maryland School of Medicine.

Received for publication March 12, 1991; revised April 19, 1991; accepted April 24, 1991.

6/1/30676

was 1035 µg. A low-dose 48-hour dexamethasone suppression test failed to suppress production of urinary free cortisol.

Before completion of endocrine evaluation, the patient threatened to leave the hospital against medical advice if the pregnancy was not terminated. Pregnancy termination was accomplished uneventfully with the use of intracervical laminaria and prostaglandin E2 vaginal suppositories. Fentanyl epidural analgesia was provided early in the course of labor induction to minimize the sympathetic nervous system's hypertensive response to pain. She was delivered of a normal-appearing but small-for-gestational age fetus weighing 70 gm; the placenta was histologically normal but correspondingly small at 35 gm. Radiographic evaluation of the pituitary and adrenal glands with computerized axial tomography was undertaken because of the patient's demonstrated lack of compliance; it revealed a 2 × 3 cm right adrenal nodule. When this information was used as a confrontational device, the patient agreed to further biochemical evaluation, which was performed 8 days post partum. It revealed that the serum corticotropin level was <20 pg/ml. Sequential low-dose 48hour and high-dose 48-hour dexamethasone suppression tests failed to suppress urinary free cortisol and 17-hydroxycorticosteroid levels. The patient underwent right adrenal exploration, and right adrenalectomy yielded a 3 × 2 × 1.7 cm benign cortical adenoma. Her postoperative course was uncomplicated, and she was discharged on a regimen of clonidine and prednisone replacement therapy. She has subsequently done well with complete resolution of clinical symptoms and biochemical derangements.

Comment

The occurrence of pregnancy in a case of untreated Cushing's syndrome is rare because of the high incidence of ovulatory disturbances associated with the disorder.1 As illustrated in this report, diagnosis is difficult because of the development of a physiologic hypercortisolism in normal pregnancy and the affective changes

in the cushingoid patient's mental status, which lead to noncompliance with medical evaluation.

Maternal morbidity associated with Cushing's syndrome is excessive, with hypertension and glucose intolerance being the most common complications.2 Congestive heart failure, proximal myopathy, depression, and poor wound healing also are noteworthy. Death has occurred in three instances.2 Pregnancy outcomes are associated with high perinatal morbidity and mortality rates, with prematurity rates approximating 60%.2 In addition, fetal intrauterine growth retardation has been noted in one-fourth to one-third of all cases (unpublished observations). Perinatal mortality is equally divided between neonatal and intrauterine deaths and thus may represent the combination of complications of prematurity and the effect of a hostile intrauterine environment created by maternal disease (unpublished observations).

Therapy for Cushing's syndrome in pregnancy should be directed toward control of hypercortisolism either through chemotherapy or by surgical extirpation, because maternal and perinatal outcomes are unacceptably poor with supportive therapy alone. Great care should be taken to correctly identify the endocrine source of the disease, be it pituitary, adrenal, or ectopic production of corticotropin. Finally, Cushing's syndrome and pregnancy are rarely coincident, but the diagnosis should not be overlooked in the pregnant woman with appropriate signs and symptoms.

We acknowledge the help of Drs. George Elias and Thomas Grace in the surgical management of this case.

Bleeding after intravascular transfusion: Experimental and clinical observations

M. Segal, BSc, F.A. Manning, MD, C.R. Harman, MD, and S. Menticoglou, MD

Winnipeg, Manitoba, Canada

Characteristics of postpuncture bleeding of umbilical vessels were evaluated with an in vitro cord perfusion model and in vivo by ultrasonographic observation of bleeding duration after intravascular transfusion. Ultrasonographic determination of blood loss in vitro was very sensitive (0.01 ml/sec). In vitro blood loss varied directly with perfusion rate, but there were wide variations between cord specimens. Observed clinical bleeding occurred in 43% of cases; the duration of bleeding varied by vessel punctured, needle size, and fetal platelet count. The combined in vitro and clinical data help define the range of duration of bleeding and the probable volume of loss. (AM J OBSTET GYNECOL 1991;165:1414-8.)

Key words: Intravascular transfusion, fetal bleeding

Ultrasonography-guided percutaneous umbilical vessel puncture, first introduced by Daffos et al.,¹ has become a standard method for fetal diagnosis and therapy. Fetal bleeding from the puncture site is commonly observed by contemporary ultrasonographic methods, but little is known about the duration, volume, and character of this bleeding. The purpose of this study was threefold: to determine in vitro the volume threshold of blood loss that may be detected by ultrasonography, to determine in vitro blood loss per unit time after 22-gauge needle puncture of the umbilical vein and its relationship to cord perfusion rate, and to determine by clinical observation the duration and character of bleeding after umbilical vessel puncture done for intravascular transfusion.

Material and methods

The minimal blood loss that could be detected by real-time ultrasonography was determined by an in vitro method. A glass water bath was filled with tepid tap water and allowed to settle until all visible bubbles dissipated. A 3.5 MHz linear-array transducer was aligned to the water bath and a 22-gauge spinal needle was placed in the water bath such that the tip was submerged approximately 4 cm and visualized by ultrasonography. A 1 ml plastic syringe was filled with freshly collected citrated whole blood, and the needle shaft and tip were imaged continuously (Acuson model 128). With minimal infusion pressures, the smallest vol-

ume of blood that could be reproducibly detected was recorded.

The relationship between umbilical vein blood flow volume and blood loss was determined by an in vitro method. Umbilical cords were collected immediately after delivery in 10 women who were >36 weeks' gestation at delivery. All collected specimens were fresh, were at least 15 cm in length, and were judged to be normal on gross inspection. The umbilical vein was immediately flushed with heparinized saline solution until all visible clots were eliminated, and then catheters of maximal permissible diameter were attached to the distal and proximal ends of the umbilical vein and secured. A constant-volume perfusion pump, attached to a recirculation circuit, perfused the umbilical vein with citrated whole human blood (hematocrit 48%).

In separate experiments the relationship between infusion volumes and umbilical venous pressure was determined; the maximal venous perfusion pressure used in this study was 12 torr. After a constant-infusion loop was established, the umbilical vein was punctured as close to the perpendicular as possible with a 22-gauge needle. Care was taken not to lacerate the umbilical vein at the time of puncture. The loop of cord with the puncture site was placed gently over a funnel and graduated beaker, and the blood loss for precisely 1 minute was collected as the cord was perfused. The collected blood volume was measured with a calibrated pipette and validated with dye dilution; both yielded an error of <0.1 ml. Blood loss from the punctured umbilical vein was measured across a range of constant perfusion rates ranging from 50 to 200 ml/min. The sequence of perfusion volumes was varied randomly and all experiments were repeated in duplicate. Subsequently, the umbilical cords were frozen with the catheters in situ. After freezing at -27° C for at least 24 hours, cords were thawed and the experiments were repeated.

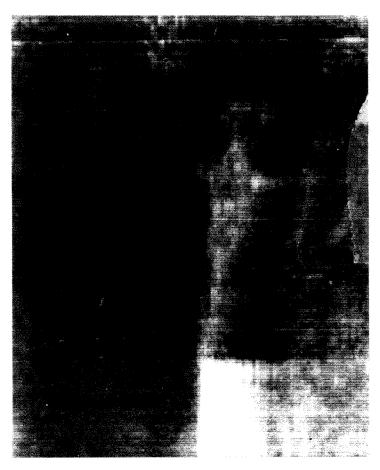

Fig. 1. Water bath image of infusion of only 0.025 ml of blood through a 22-gauge needle (bright linear echoes at left), producing turbulence.

Clinical observations of the duration of visible intraamniotic bleeding after umbilical vessel puncture were made with 3.5 MHz transducer and an ultrasonographic imaging system (Acuson model 128). Observations of bleeding time were made in 264 consecutive intravascular transfusions done because of severe fetal alloimmune disease in 72 fetuses, 23 of whom were hydropic at first transfusion. The gestational age at procedure ranged from 19 to 35 weeks. The duration of postpuncture bleeding was defined as the time between immediate removal of the needle from the fetal vessel and the inability to detect blood loss from the puncture site. In addition to duration of bleeding, qualitative characteristics of the bleeding were noted. Delivery follow-up was available on all fetuses.

Parametric statistical methods were used to assess data and included regression analysis and Student t test for unequal variance. Statistical significance was designed as a p value ≤ 0.05 .

Results

With an in vitro sequential graduated trial method, the minimal discrimination for blood loss from the tip of a 22-gauge needle by an ultrasonographic method

was 0.01 ml/sec. Above this minimal detection threshold, no direct relationship between the rate of blood loss from the needle tip and the ultrasonographic characteristics could be identified (Fig. 1).

The rate of blood loss from punctured perfused umbilical vein segments in vitro was related in a direct and linear fashion to the umbilical vein perfusion rate (r = 0.873, p < 0.01) (Fig. 2). In duplicate studies on the same vein at different perfusion rates, the mean variation between repeat experiments was 0.6 ml/min. In combined observations blood loss (mean ± SEM) from the puncture site ranged from as low as 2.99 ± 0.43 ml at a 50 ml/min perfusion rate to as high as 6.77 ± 0.64 at a perfusion volume of 200 ml/min (Table I). Blood loss varied widely from one fresh cord segment to another, ranging from 0.3 to 8.3 ml/min at the 50 ml perfusion rate, 0.5 to 10.13 ml/min at the 100 ml perfusion rate, 1.3 to 14.08 ml/min at the 150 ml perfusion rate, and 1.68 to 18.4 ml/min at the 200 ml perfusion rate. Within individual cord specimens, blood loss increased with incremental increases in infusion rate in 52 of 60 observations (86.6%), was not measurably different in five observations (8.3%), and decreased in three observations (5%). Standardization

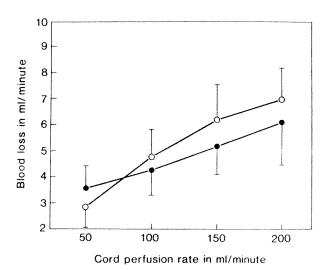

Fig. 2. Relationship between blood loss per 22-gauge puncture of umbilical vein and rate of perfusion of vein. In vitro experiments were done in 10 fresh cords (open circles) and after freezing (closed circles). Blood loss did not vary between fresh or frozen cords and bore a direct and significant relationship to perfusion volume (r = 0.873, p < 0.01).

of blood loss by using the percent change per incremental increase in perfusion rate yielded a significant inverse linear relationship between percentage loss and perfusion rate (r = 0.757, p < 0.01).

Clinical observations were made in vivo immediately after needle removal in 264 intravascular transfusion procedures (packed cell transfusion, hematocrit ≥85%, average transfusion volume of 50 ml/kg estimated fetal weight). In 152 instances, the cord vessel puncture was on the placental side of the vessel and intraamniotic bleeding was not observed. In 112 cases (43.2%) cord puncture was transamniotic, and back-bleeding occurred, permitting determination of intraamniotic bleeding time and character. Data from these 112 procedures were analyzed.

Postpuncture bleeding characteristics were assessed both qualitatively and quantitatively.

Qualitative characteristics. The characteristics of postpuncture bleeding appear to vary by the vessel punctured. Venous bleeding was characterized within the amniotic space by an immediate showering of echodense material that gravitated toward the dependent portion of the uterus. The ultrasonographic echos were most evident and dramatic at immediate needle removal and gradually diminished in a decrescendo pattern until disappearance. It was common to observe a continued slow and sometimes intermittent showering preceding complete cessation of visible bleeding. Arterial bleeding was distinctly different on ultrasonographic scanning. Needle removal was associated with a plume of blood that often projected up, struck the

chorionic plate, and showered back. The characteristic pluming effect seemed to persist unabated for a period of time and then ceased abruptly. Evidence of slow bleeding from arterial puncture sites was infrequent.

Quantitative analysis. Eighty-five umbilical vessel puncture procedures were done with a 22-gauge needle in 72 venipunctures and 13 umbilical artery punctures. The mean observed bleeding time for 22-gauge umbilical vessel puncture was 137 seconds (range 5 to 720 seconds) (Table II). Bleeding time varied significantly by the vessel punctured; the mean bleeding time was 144 seconds (range 5 to 450 seconds) after venipuncture (n = 72) and 95 seconds (range 5 to 720 seconds) after arterial puncture (n = 13) (p < 0.05).

Twenty-seven umbilical vessel punctures were done with a 20-gauge needle, 22 of which were venipunctures and 5 were umbilical artery punctures. The mean bleeding time after 20-gauge umbilical vessel puncture was 92 seconds (range 5 to 300 seconds). The mean duration of venous bleeding in 22 instances was 102 seconds (range 20 to 350 seconds), and in 5 cases of arterial puncture mean duration of bleeding was 48 seconds (range 5 to 300 seconds).

Fetal platelet count was determined in 110 of 112 procedures and was related to the duration of post-puncture bleeding. Fetal platelet count was normal in all 27 procedures done with a 20-gauge needle. In 83 of the 85 procedures done with a 22-gauge needle, fetal platelet count was available. In 75 instances the fetal platelet count was normal (platelet count $\geq 50,000/\text{ml}$) (range 80 to 400,000/ml); the mean bleeding time in these cases was 123 seconds (range 5-400 seconds). In eight procedures the platelet count was abnormal (6000/ml) to 49000/ml); the mean bleeding time in fetuses with thrombocytopenia was 373 seconds (range 140 to 720 seconds). These differences were significant $(p \leq 05)$.

In nine fetuses a clinical diagnosis of fetal exsanguination was made on the basis of a combination of findings, including prolonged bleeding (≥300 seconds) of a quantitative nature judged to be severe. All fetuses had gross abnormalities of fetal heart rate and loss of other biophysical variables. Two of these fetuses (31.6 and 32.5 weeks, respectively) were delivered by prompt cesarean section, were severely anemic and volume depleted at birth, but responded to resuscitation and survived. The remaining 7 fetuses were <32 weeks at diagnosis of fetal exsanguination (age range 21 to 31 weeks). In three of these fetuses immediate prompt repeat intravascular transfusion was done, including in one fetus with intracardiac transfusion, and all responded promptly to volume replacement and survived. In the remaining four cases (all <24 weeks' gestation), immediate vascular access could not be rees-

tablished and all fetuses died promptly. Death was attributed to severe hypovolemia and cardiovascular collapse.

Comment

From our clinical observations we noted that all procedures in which umbilical vessel puncture occurred distal to the chorionic plate and placental substance (43% of total procedures), bleeding was detected by real-time ultrasonographic methods. The in vitro experimental observations offer insight to the nature of this bleeding.

The detection of egress of blood from a 22-gauge needle by dynamic ultrasonography was surprisingly sensitive; in these studies the minimal volume threshold for detection was at least as low as 0.01 ml/sec. Whereas unclotted whole blood is more echo dense than amniotic fluid or saline solution, these media in a static state cannot be differentiated by ultrasonography. In the dynamic state these minor differences in echo density become amplified to the observer, and blood is easily identified by its specular echo density pattern as it falls down through the water medium. From these titrated observations it is evident that detection of bleeding by ultrasonography is sufficiently sensitive to be of clinical usefulness in timing the duration of the event. Whereas qualitatively larger-volume bleeding tends to produce wider and more spectacular echo-dense patterns than bleeding of lesser volume, these differences are highly subjective and not possible to quantitate. Thus it is disappointing to note that from these in vitro observations the rate and volume of bleeding after vessel puncture cannot be quantified by ultrasonography to an accuracy level that is clinically useful.

In our experience most umbilical vessel punctures for diagnostic or therapeutic reasons are done at gestational ages at or below 30 weeks. Direct measurements of umbilical blood flow in the ovine and porcine fetus are reported as 160 to 2001 and 160 to 170 ml/min, respectively,2 and by indirect ultrasonographic calculation methods to be 110 to 120 ml/min in the human fetus.3 The constant volume perfusion rate of the um-

bilical vein in vitro used in this study would approximate the expected flow observed in human fetuses with weights from 500 to 1750 gm, the usual weight range of fetuses subjected to in utero umbilical vessel puncture.

Major differences between the in vitro model in this study and the clinical circumstance must exist. In the cord perfusion model bleeding from the puncture site was observed to be relatively constant. In contrast, qualitative observation of postpuncture bleeding in the human fetus demonstrated a decrescendo pattern of loss, evident in observation of both venipuncture and arterial puncture and most dramatic in the latter. Occlusion of the puncture site in vivo may be the result of platelet and fibrin accumulation, local vessel spasm at the site of puncture, or both. The in vitro studies demonstrated no difference in bleeding rate between fresh and frozen cords, which may indicate that vessel wall changes are of lesser importance than local coagulation. The clinical observation of significantly prolonged bleeding in human fetuses with thrombocytopenia may suggest that platelets are important in limiting postpuncture bleeding.

[†]Compared with next lowest perfusion rate, p < 0.05.

The pure physics model would predict that within a constant pressure range egress from a perpendicular puncture of fixed aperture would vary in a direct linear manner with flow rate. The observation of the in vitro cord perfusion model approximates the theoretic model (Fig. 2). However, whereas an increase in perfusion was generally associated with an increased loss in individual experiments, wide variation between cord specimens was observed (Table I). The explanation for this variation is not clear because aperture size, perfusion rates, and perfusion pressures were well controlled. It is possible that the holes produced by the needle were not uniform or that vein friability resulted in enlargement of the hole when subjected to perfusion pressure. If such were the case, it was not visible by inspection of the puncture site. Whatever the reason for the individual variation, the phenomenon is important in interpreting probable blood loss in vivo. Total fetal blood loss after vessel puncture, the salient clinical point, must be the product of rate and duration of bleeding. Since the threshold for detection of bleeding by ultrasonography is so low, it follows that measurement of duration of bleeding is likely to be very accurate. In the clinical part of this study postpuncture bleeding was noted also to vary widely; mean duration of bleeding was significantly greater with venipuncture, was significantly prolonged in fetuses with disease severe enough to cause thrombocytopenia, and varied significantly between a 20- and 22-gauge aperture. Given the inability to quantitate blood loss by ultrasonography, the individual variability in loss per cord specimen, the variability in duration of bleeding, and the lack of precise information on cord perfusion rate and pressure, in vivo calculation of actual blood loss is impossible. It is also clear from the clinical observations in the study that life-threatening fetal exsanguination can result from postpuncture bleeding.

In spite of these limitations of measurement error, combining the in vitro and in vivo observation may offer some insight into the usual expected loss and the extremes that may occur. For example, using mean venipuncture bleeding time (144 seconds or 2.4 minutes) as the basis for comparison, the average expected blood loss across the perfusion range of 50 to 200 ml/min would be 5 to 6 ml at the 50 ml/min rate to 12 to 13 ml at the 200 ml/min perfusion rate. Average loss in the fetus is likely to be less than these estimates in view of the observed decrescendo pattern of bleeding. With

the assumption of an average fetal blood volume of 125 ml/kg and a direct relationship between fetal weight and umbilical blood flow,³ average losses of these magnitudes would be <5% of total fetal blood volume. In contrast, with maximal observed loss figures from the in vitro observations, in vivo loss for the fetus could be as high as 19 to 20 ml at the 50 ml perfusion rate and as high as 44 to 45 ml at the 200 ml perfusion rate; these losses could represent up to 20% to 25% of total blood volume. Such loss may cause fetal anemia but is unlikely to cause irreversible hypovolemia.

The duration of fetal bleeding also must be a critical component of hemorrhagic fetal compromise after vessel puncture. In the clinical observation in this study the maximal duration of bleeding was 720 seconds (12 minutes). Bleeding of this duration could yield an average net blood loss of 28 to 30 ml at 50 ml/min perfusion to 62 to 63 ml at 200 ml/min perfusion, representing ≥50% of fetal blood volume. Combining prolonged bleeding time with maximal cord loss observation could yield fetal blood loss of up to 90 ml at the 50 ml/min perfusion rate up to 220 ml at the 200 ml/min perfusion rate; bleeding of the magnitude would certinaly lead to hypovolemic collapse.

These combined clinical and experimental data offer some insight into the extent of fetal bleeding after vessel puncture and may be of some value in clinical application. It is evident that in the average case blood loss is likely to be minimal and not to exceed 5% to 10% of total blood volume. It is equally evident that prolonged bleeding, either spontaneous or in the presence of thrombocytopenia, may result in exclusive fetal loss up to as much as 30% to 90% of total fetal blood volume. The exact determination of loss would appear to be beyond conventional ultrasonographic measurement capabilities. Planned studies of amniotic fluid blood content or serial changes in fetal hematocrit are planned and may shed additional light on this common procedural complication.

Recombinant 8 syndrome: The pool of Hispanic pericentric inversion 8 carriers expands numerically and geographically

Luis A. Izquierdo, MD, Thomas S. McConnell, MD, Luis B. Curet, MD, and Gloria E. Sarto, MD, PhD^a

Albuquerque, New Mexico

Recombinant 8 syndrome is a well-established syndrome with mental and developmental retardation and usually severe cardiac anomalies. A carrier parent will produce affected offspring in 6% of pregnancies and carrier offspring in 53% of such pregnancies. Four New Mexican kindreds ascertained by the discovery of four apparently unrelated probands with cytogenetically confirmed recombinant 8 syndrome were studied. We found that (1) recombinant 8 syndrome will soon no longer be confined to New Mexico and southern Colorado, (2) the number of persons at risk may be higher than previously considered, and (3) through proper pedigree techniques and increased professional education, most carriers can be identified. (AM J OBSTET GYNECOL 1991;165:1419-22.)

Key words: Recombinant 8 syndrome, chromosomal aberration, mental retardation

Rec(8),dupq,inv(8)(p23q22) is a chromosomal aberration causing a well-established dysmorphic syndrome with mental and developmental retardation and usually severe cardiac anomalies.1-3

The first case of a child born with the characteristic duplication-deletion of chromosome 8 was described by Fujimoto et al.1 Since then, many more cases have been discovered and described. The most recent report was by Smith et al.4 at the University of Colorado.

All of the children were from the southwestern United States with Hispanic ancestry, and all were diagnosed as having congenital heart disease and dysmorphic features. Chromosomal analyses showed dupq,inv(8)(p23q22), an unbalanced recombinant that arises through meiotic recombination of a normal chromosome 8 and chromosome 8 with a pericentric inversion, in one of the affected child's parents.⁴⁻³

Carriers of the pericentric inv(8) appear to have no phenotypic abnormalities. The recombinant 8 chromosome results in a dysmorphic syndrome characterized by congenital heart disease, ranging from a small ventricular septal defect to classic tetralogy of Fallot, developmental and mental retardation, hirsutism, cleft lip and palate, raised nasal bridge, flat nose, elongated philtrum, prominent lateral folds along each side of the nose, hypertelorism, short wide neck, short stature, and fifth-finger camptodactyly3 (Fig. 1). Through the work

Fig. 1. Male child with recombinant 8 syndrome showing square face, low frontal hairline, long palpebral fissures, broad high nasal bridge, upturned nose, and square earlobes.

of collaborators at the University of New Mexico and the University of Colorado,24 the number of carrier

Hispanic families ascertained has increased. The risk

of an inversion carrier passing on the inv(8) chromo-

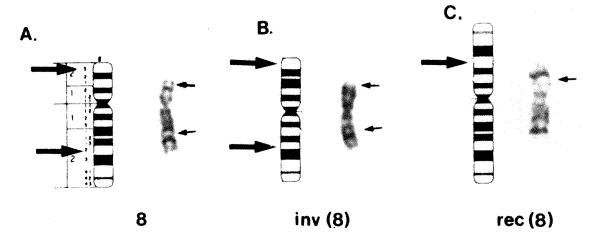

Fig. 2. Idiogram of chromosome appears on left of each pair; actual banded chromosomes on right. *Arrows* denote breakpoints. **A,** Normal chromosome 8; **B,** carrier, inv(8)(p23q22); **C,** affected, rec(8),dupq,inv(8)(p23q22).

some to a child is approximately 53% (59% from mothers, 42% from fathers) while that of rec(8) is calculated as 6.2%. On the basis of these data, a prospective investigation to gather additional data on the existing pedigrees both vertically (increased generations) and horizontally (increased numbers of individuals) was performed. The intent was to test older people in the pedigrees in the hope of linking older generations and to test younger people in the pedigrees who were planning to start families. Those shown to be inversion carriers would be offered genetic counseling and prenatal diagnosis.

Material and methods

Four New Mexican kindreds ascertained by the discovery of four apparently unrelated probands with cytogenetically verified recombinant 8 syndrome were evaluated. Family pedigrees were expanded by obtaining information during home visits to family members in Albuquerque and several northern New Mexico villages and from patients visiting the fetal diagnosis and therapy clinic at the University of New Mexico Hospital. Cytogenetic analysis was performed by standard Giemsa-trypsin banding methods of peripheral blood lymphocytes and amniotic fluid cell cultures. ^{3, 6}

Peripheral lymphocytes obtained by venipuncture from 23 patients and amniotic fluid from one patient were analyzed cytogenetically. Diagnostic procedures were performed at the University of New Mexico Women's Specialty Clinic. Statistical evaluation was performed by χ^2 analysis as a test for goodness of fit of the expected risks.

Results

From July 1988 through June 1990 we evaluated 28 individuals. Of these, 4 (14%) had the recombinant 8

syndrome and 24 had normal phenotypes. Cytogenetic analysis of the 24 phenotypically normal family members showed that 11 (46%) carried the pericentric inversion of chromosome 8 and that 13 (54%) had normal karyotypes (Fig. 2, *A*, *B*, and *C*). Prenatal cytogenetic diagnosis offered to one carrier couple at risk showed a 46,XX fetus.

The χ^2 analysis of the frequency of pericentric inv(8) in this group of individuals was not significantly different (1 df resulted in a value of 0.495 with a p value of 0.48). The χ^2 analysis for the risk of rec(8),dupq,inv(8)(p23q22) probands during this study resulted in a value of 2.283 with a p value of 0.130, which is not statistically different from that of previous studies.

With these four pedigrees added, the total number of kindreds in New Mexico is 12. Two pedigrees were traced back six generations linking these two kindreds at the sixth-generation ancestor level (Fig. 3). One other kindred arose in a tiny northern New Mexico village where three previous families have been linked.

Two thirds of these four kindreds' progeny live away from New Mexico: Texas, Arizona, California, Oregon, Illinois, Maryland, Tennessee, and Virginia (Fig. 4).

Comment

Chromosomal inversions fall into two groups, pericentric and paracentric. In pericentric inversion the two breaks that originally preceded the inversion are in opposite arms.⁷ In paracentric inversion they are in the same arm. Before chromosomal banding techniques, pericentric inversions were discovered by the altered position of the centromere, relative to the distance to either telomere. Chromosomes vary with which arm inversion is likely to occur; for instance, inversion in chromosome 9 accounts for 40% of all inversions.⁴ The

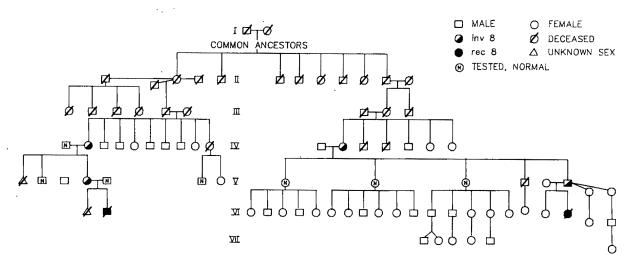

Fig. 3. Pedigree linking two families. Note carrier parents in generations IV and V, discovered by parental testing of probands. Deceased carriers are linked by noting relationships of obligate carriers.

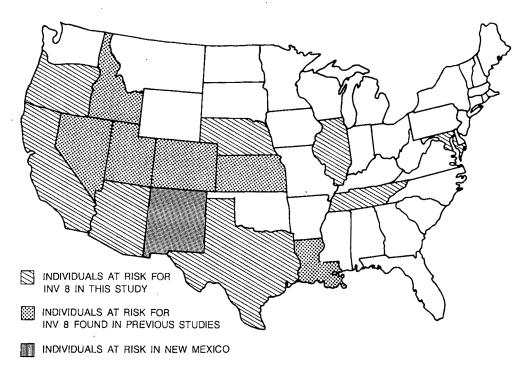

Fig. 4. States in which inversion 8 kindreds have been identified.

location of the break points occurs along the length of the chromosome in a nonrandom fashion. During meiosis, short heterozygous inversions remain unpaired. A large inverted segment usually forms a loop to pair with its homologue, or it may pair straight, leaving the now nonhomologous ends unpaired. Crossing over in a pericentric inversion leads to a deletion and duplication, a phenomenon called aneusomie de recombinaison by French authors.8 The larger the inversion, the more likely the recombination duplication-deletion will occur. Both duplication and deletion may give rise to abnormal but viable offspring. It is surprising how

few of the inversions in man seem to lead to reproductive abnormalities, either by the birth of recombinant offspring or by partial sterility.7-9

The prevalence of recombinant 8 syndrome in the southwestern United States is continually growing. There are affected children in all southwestern states, as well as known carriers and other family members in most of the rest of the United States. Until recently, the families who migrated from New Mexico and Colorado have all been of Hispanic origin, but through intermarriage, there are now members of other groups at risk as well.4 This study shows that the number of 1422 Izquierdo et al.

people currently at risk for carrying inv(8)(p23q22) and those having children with severe congenital anomalies is greater than previously expected. The actual numbers of carriers and people at risk in New Mexico are no less than those calculated. Still, many branches of the pedigrees are incomplete, and some go back eight generations. We linked two apparently unrelated families at a sixth-ancestor level, supporting the theory of a common founder at least 350 years ago in the southwestern United States.3 There is a single report of a Hispanic child with recombinant 8 syndrome and rec(8) chromosome in the Argentinean literature.10 This finding suggests a founder earlier than our current estimation, perhaps from Spain. We have been unable to obtain a pedigree on this family. Given that the risk for inheritance of the pericentric inversion is approximately 50% and that there is no effect on the health or fertility of these carriers, we can expect a geometric increase in the number of both carriers and affected children in the next decade.

The large number of carriers and people at risk in these families and the many as yet incomplete branches in these pedigrees point to a need for follow-up of these families, completion of the pedigrees, testing of possible carriers, and provision of genetic counseling and follow-up for concerned parents. The basic dysmorphic features of the affected children should be diagnosable by high-resolution ultrasonography.11 These features include congenital heart defects, cleft lip and palate, elongated philtrum, and hypertelorism. Physicians working in the southwestern United States who evaluate patients with a history of mental retardation and heart defects should include recombinant 8 syndrome in their differential diagnosis. In fact, at the University of New Mexico Medical Center, congenital heart defect and southwestern United States Hispanic ancestry are an indication for cytogenetic analysis.

Further work with this problem should include ex-

panding the existing family pedigrees to identify additional members and risks of carrying the inversion, performing chromosome analysis on the large number of individuals who we have identified to be at risk, ascertaining additional children in known or new families with recombinant 8 syndrome, gaining more knowledge concerning the proper treatment and the most effective educational approaches for affected children, and educating physicians and the general public about this syndrome.

Subchorionic hematomas and the presence of autoantibodies

Laxmi V. Baxi, MD, and Melissa M. Pearlstone, MD

New York, New York

Five cases of subchorionic hematoma detected by ultrasonography in patients with threatened abortion are presented. Three of these subjects had antinuclear antibodies, and the remaining two subjects had anticardiolipin antibodies. We recommend that patients with subchorionic hematomas be tested for autoantibodies regardless of their obstetric history. (AM J OBSTET GYNECOL 1991;165:1423-4.)

Key words: Subchorionic hematoma, autoantibodies, anticardiolipin antibodies, antinuclear antibodies, habitual abortion

Lupus and allied disorders, as well as anticardiolipin antibodies, are associated with poor fetal outcome. Recently, a high prevalence of antinuclear antibody—positive serum was demonstrated in patients with recurrent pregnancy losses. The incidence of anticardiolipin antibody in the general obstetric population is 1% to 2%; it is approximately 40% in patients with a poor obstetric history.

6/1/30675

In this manuscript we describe five cases of subchorionic hematomas that were associated with autoantibodies. The patients presented with vaginal bleeding in the late first trimester or early second trimester of pregnancy. The clinical details are summarized in Table I.

Three of these patients had had one or more spontaneous abortions. One of the remaining two patients was primigravid; the other had had an induced abortion. In all these patients subchorionic hematomas were detected by ultrasonography that was performed because of threatened abortion. Anticardiolipin or antinuclear antibodies were also detected.

The presence of vaginal bleeding during early pregnancy is associated with a 10% to 15% risk of spontaneous abortion. The incidence of a subchorionic he-

	Bleeding at 11 wk, subchorionic hematoma persisted	ACL Ab (+)	Aspirin 75 mg daily begun at 13 wk	Neonatal death at 24.8 wk

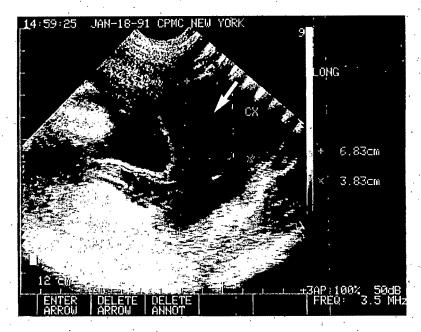

Fig. 1. Arrow points to subchorionic hematoma.

matoma detected by ultrasonography in women with threatened abortions varies widely (11% to 62%). Several studies have demonstrated that patients who have a subchorionic hematoma are more likely to abort (13% to 40%). Pedersen et al. Suggested that the high rate of spontaneous abortions (40%) observed in subjects with subchorionic hematomas may have been due to a patient selection bias (most of those patients had a poor obstetric history). This theory is supported in a study by Mandruzzato et al., who found that 50% of women who presented with an intrauterine hematoma had had a previous spontaneous abortion. In any case, the etiologic and epidemiologic factors of subchorionic hematomata remain unclear.

We propose that the presence of autoantibodies may be an etiologic factor. These antibodies may increase the tendency of platelets to aggregate, which leads to thrombosis and/or vasculitis and thereby to an increased likelihood of a subchorionic hematoma. Although subplacental bleeding in patients with lupus has been reported, subchorionic hematomas have not been described.

We recommend that patients with threatened abortion and subchorionic hematomas detected by ultrasonography (Fig. 1) be evaluated for autoantibodies, regardless of obstetric history. Those patients with a poor obstetric history and persistent hematomas should be treated aggressively with low-dose aspirin and/or corticosteroid medications.

The dimension of chaos in the fetal heart rate

David G. Chaffin, MD, Cynthia C. Goldberg, MSIV, and Kathryn L. Reed, MD

Tucson, Arizona

Variability in the fetal heart rate is known to be a sign of fetal well-being, and yet the origins of the variations remain unclear. This study incorporated the nonlinear analytic techniques of phase-space reconstruction and dimensional analysis to 12 normal heart rate tracings obtained from fetal scalp electrodes of fetuses in labor. Phase-space attractors were constructed with the method of time delays and showed characteristics consistent with those of nonlinear chaotic systems. Dimensional analysis resulted in three distinct groups being identified. Results indicate that control of the fetal heart rate may be modeled as a nonlinear or chaotic system, and analytic techniques borrowed from the physical sciences are useful in exploring heart rate variability. That different groups could be distinguished among qualitatively similar heart rate tracings may lead to understanding of discrepancies between evaluation of the monitor tracing and neonatal outcome. (AM J OBSTET GYNECOL 1991;165:1425-9.)

Key words: Chaos, dimensional analysis, nonlinear, heart rate variability

Fetal heart rate (FHR) variability was first recognized as being clinically important by Hon,1 Hammacher et al.,2 and Caldeyro-Barcia et al.3 in the early 1960s, and the intervening years have seen intensive research into the underlying source of the variations.4 Numerous statistical indices have been developed for quantifying variability,5-7 and various physiologic models involving the integration of the autonomic, humoral, and central nervous systems have been proposed.4 The central tenet of this article is that the limitations of the above approaches derive from the constraint of linearity. In linear systems the measured variable (such as heart rate) is presumed to be the weighted sum of the various factors that influence that variable. In general, small perturbations of the controlling factors will give small changes in the measured variable. In contrast, in a nonlinear system no such presumption is made. A nonlinear system may give rise to chaos where long-term predictability is impossible, and small perturbations may result in radically new behavior in the measured variable.8.9 Recent work in systems ranging from the intact adult human10 to myocardial cell aggregates11 suggests that control of heart rate may be best described with nonlinear dynamics. With phase space reconstruction (plotting each R-R interval vs the R-R interval after a fixed delay), West and Goldberger10 obtained graphs (attractors) suggesting that the fluctuations in a normal heart rate are typical of a chaotic nonlinear system. They showed that as disease progresses there is a loss

Fig. 1. Phase-space attractor from case 4. Successive values of FHR are plotted against those 10 beats later.

of this chaotic nature, ultimately leading to a stable point (no variability) immediately preceding death. In studies of periodically perturbed, spontaneously contracting aggregates of myocardial cells Guevara¹¹ has found period doubling and phase locking, features that are consistent with nonlinear dynamics. This article attempts to show that tools traditionally used in the analysis of nonlinear dynamic systems, including phase-space graphs and dimensional analysis, may be applied to FHR variability.

Material and methods

Heart rate data were obtained from scalp electrodes on 12 fetuses at term, in labor, with an FHR tracing (FHT) pattern considered reactive by the management team. All fetuses were delivered in good condition with

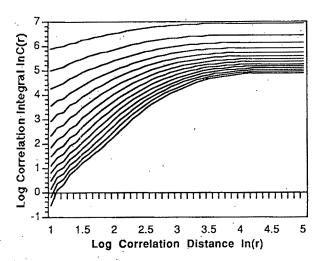

Fig. 2. Log/log plot of correlation integral versus distance for case 4. Each curve is plot of lnC(r) versus distance at embedding dimensions 2 through 15. Slope of linear region of each curve between 2 and 3.5 on ln(r) axis is correlation dimension v for corresponding embedding dimension.

a 5-minute Apgar score >8. The electrodes were attached to a Corometrics 112 cardiotocodynamometer, which strobes a voltage proportional to the R-R interval of the fetal electrocardiogram onto a port at the back of the machine. This voltage was digitized at 12 bits of precision, with a GW Instruments A/D converter with an effective precision of ± 1 beat/min. A total of 5000 heartbeat intervals for each fetus were stored on a Macintosh computer for off-line analysis.

Phase-space attractors were created by using a time-delay technique to produce a two-dimensional vector from a one-dimensional time series. FHT at time t is plotted against FHT at time t+10 beats, with a delay of 10 beats empirically chosen as giving the best resolution of detail (a representative attractor is shown in Fig. 1).

Dimensional analysis was performed by means of the method of Grassberger and Procaccia. ¹² Briefly, a point in n-dimensional phase space may be formed by n successive time-delayed values of the FHT, where the time delay k=10 beats:

[FHT (t), FHT (t + k), FHT (t + 2k), ..., FHT
$$(t + nk)$$
]

For each n-dimensional phase space, n=2 to 15 (5000 -n) points were so created; this is the process of embedding the FHT in the n-dimensional space. For example, the attractor in Fig. 1 is embedded in two dimensions (with [FHT (t), FHT (t+10)]). Within each embedding dimension, the distance (r) of each point to every other point was then calculated. The range of distances, from the smallest to the largest, was broken up into discrete intervals, and the number of times a distance fell within an interval was counted. From this

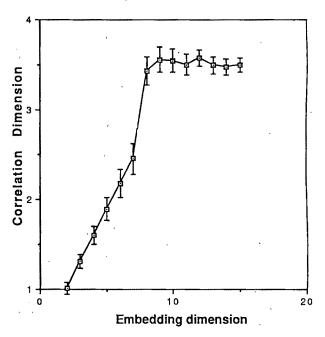

Fig. 3. Correlation dimension (\pm SE) versus embedding dimension for case 4. Plateau region beginning at embedding dimension 9 is well defined (mean, 3.519 ± 0.016).

Table I. Calculated dimensions of attractors

histogram the cumulative histogram was formed by summing the number of instances that a distance was less than or equal to the upper boundary of the interval. For example, the value of the cumulative histogram at 0.0498 is the count of the number of instances that an interpoint distance (r) was ≤ 0.0498 . This cumulative histogram is the correlation integral C(r). The logarithm of the correlation integral was then plotted against the logarithm of the distance, resulting in the sigmoid-shaped curve expected of a chaotic attractor. In the linear portion of the curve the correlation integral should scale as lnC(r) = vlnr, where v is the dimension of the attractor. The slope (v) of the linear portion of the curve was calculated with simple linear regression over the longest segment with a regression

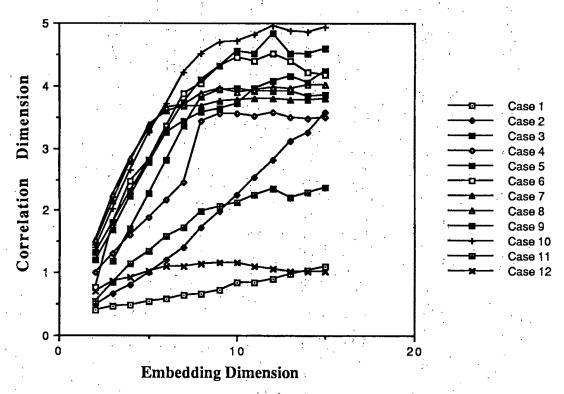

Fig. 4. Correlation dimension versus embedding dimension for 12 fetuses.

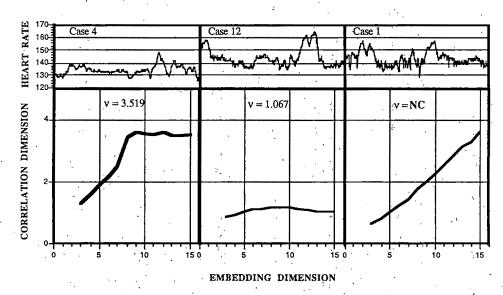

Fig. 5. Comparison of illustrative cases from three categories of dimension, v, with associated FHTs. NC, Not calculable.

coefficient $R^2 > 0.98$. This process was carried out for successively higher embedding dimensions (n = 2 to 15). Where a plateau was observed in the plot of the correlation dimension versus the embedding dimension, the value of the plateau was calculated with a weighted average technique where each value in the

plateau region is weighted by the variance of the underlying slope calculation.

Results

Random noise is uncorrelated over all characteristic distances and in phase space shows no structure; a lin-

ear system would have a very simple structure, either a point or a closed curve.¹³ However, a complicated structure is clearly evident in the attractor depicted in Fig. 1. The structure is also qualitatively similar to the attractor obtained from the heart rate of a normal adult.¹⁰

A typical plot for one fetus of the log of the correlation integral [lnC(r)] versus the logarithm of the distance [ln(r)] for embedding dimensions 2 to 15 is shown in Fig. 2. The linear portion of each curve is termed the scaling region. The slope of the scaling region for each curve was calculated and the results were plotted against the embedding dimension in Fig. 3. Noise, or a purely stochastic process, results in slopes that continue to increase without bound as the embedding dimension increases, whereas a linear system would give an integral correlation dimension. However a nonintegral plateau region is clearly seen, implying that a low-dimensional attractor is present, and the dimension of this attractor is 3.519 ± 0.016 as calculated from the weighted average of the plateau values. The results of similar plots for all 12 fetuses are shown in Fig. 4 and the resulting dimensional calculations are shown in Table I. Three distinct states are noted: a low-dimensional attractor with a correlation dimension between 3 and 5 (cases 3 through 10), a low-dimensional attractor of dimension ≈1 (cases 11 and 12), and an uncalculated dimension in two cases (a dimension could not be calculated because the correlation integral continued to increase with increasing embedding dimension [cases 1 and 2]). FHTs and correlation dimension versus embedding dimension graphs representative of the three subsets are illustrated in Fig. 5.

Comment

Previous attempts to analyze the variability present in the FHR have either concentrated on statistical descriptions of the time series⁵⁻⁷ or, using the Fourier transform, reported information on the power spectrum.4 Both of these methods of analysis rely on a linear model of FHR control. The statistical descriptions were developed without an attempt to explain the underlying influences, and although the descriptions appear reliable in quantifying short-term variability, they fail to account for long-term variability and are no better than a trained clinical observer. Spectral analysis models the control of the heart rate as the linear combination of a variety of physiologic inputs and attempts to quantify the role played by each (parasympathetic, sympathetic, thermoregulatory, etc.) by the amount of spectral power at a characteristic frequency. The underlying assumption of spectral analysis models is that heart rate variability will change as a linear function of changes in spectral power at certain frequencies.

The results presented in this article suggest the FHR is inherently nonlinear in nature and that there is in-

formation to be gained from characterizing the behavior of the dynamics of heart rate in phase space. A suggestion that this is a reasonable approach came from visual inspection of the two-dimensional plot, which is clearly not a simple limit cycle (circle) and neither is it consistent with noise (i.e., a scattergram). Linear systems are limited in the structures they can display in phase space to a simple circle (or smooth deformation of a circle, such as an ellipse), whereas chaotic systems may have rather bizarre paths (attractors) in phase space.18 One way to characterize an attractor is by quantifying the dimension,12 which can be viewed as an approximation of the number of variables needed to describe the dynamics. It is characteristic of chaotic (as opposed to stochastic) dynamics that the dimension of the attractor in phase space is less than the dimension in which it is embedded. It is not the purpose of this article to assert that the resulting number has any independent meaning in and of itself (given the limitations of noise, measurement inaccuracy, and small data sets); rather the point is that the FHR exhibits nonlinear dynamics (chaos) and is amenable to analytic techniques differing from those for the traditional linear model.

In this report the FHTs would be interpreted as reactive by conventional criteria, and each labor resulted in a vigorous newborn. However, dimensional analysis revealed several distinct subcategories, which may correspond to different physiologic states that are indistinguishable by simple inspection of the monitor tracing. Fifty percent of fetuses with an abnormal FHT (late decelerations) have no evidence of acidosis at birth14; dimensional analysis may be able to distinguish an acidotic fetus from a normal fetus in such cases. Whereas further studies will be necessary to characterize the physiologic and clinical correlates of these measures of phase-space dynamics, this study suggests that nonlinear analysis of human fetal physiologic characteristics may be a fruitful alternative to more traditional models.

Identifying pregnant women who drink alcoholic beverages

Patricia Dolan Mullen, DrPH,^a Joseph P. Carbonari, EdD,^b and Marianna C. Glenday, MPH^a

Houston, Texas

This randomized 2×2 study compared disclosure rates of alcohol use with two response formats (multiple choice and dichotomous) and two communication channels (oral and written) in an adult prenatal population (N = 1078). The multiple choice question improved disclosure, regardless of channel, by 40% across white, African-American, and Hispanic subgroups. (AM J OBSTET GYNECOL 1991;165:1429-30.)

Key words: Prenatal risk assessment, prenatal history taking, self-reported alcohol consumption

Obstetricians need accurate information about their patients' alcohol consumption. Many pregnant women do not report use of alcohol, and some physicians are reluctant to broach this sensitive area. Available screening tools for general patient populations are not very helpful with pregnant women and provide information only about abusive drinking or alcoholism. Therefore we tested a question to identify all pregnant drinkers of alcohol, regardless of amount of consumption.

Material and methods

Two response formats ("yes or no" and multiple choice, Table I) and two channels of questioning (oral and written) were compared, by means of a random-

6/1/30442

Table I. Multiple choice question

Which of the following statements best describes your use of any alcoholic beverages, including beer, wine, and hard liquor?

Would you say:

- I drink regularly now—about the same amount as before finding out I was pregnant.
- 2. I drink regularly now, but I've cut down since I found out I was pregnant.
- 3. I drink every once in a while.
- 4. I have quit drinking since finding out I was pregnant.
- 5. I wasn't drinking around the time I found out I was pregnant, and I don't currently drink.

ized, 2 × 2 factorial design. In all study groups we combined the alcohol history question with questions about use of automobile safety belts, smoking, and illicit drugs. All study subjects were English-speaking women ≥18 years old who were free of mental and sensory handicaps and who entered prenatal care at one of four multispecialty group satellite clinics between September 1988 and February 1990.

The experiment was conducted during the first visit after confirmation of pregnancy. The experimental questions were embedded in the oral and written history questions. Prenatal history information was stripped of identifiers before being given to university-based researchers, a procedure approved by the uni-

versity and clinic human subjects protection committees.

Results

Of 1206 pregnant women seen for care during the study, 1078 (89.4%) were eligible. The sample was Hispanic (14.7%), African-American (32.6%), and white, non-Hispanic (50.1%); married (82.5%); with a mean age of 28 years; with low parity (80.7% with <2 previous live births); and with few maternal or previous fetal or infant health problems (75.5% had none). The groups did not differ according to race or ethnicity, marital status, age, parity, or maternal health problems or fetal or maternal problems in previous pregnancies.

We used a logistic regression model for data analysis. The primary dependent variable was self-reported drinking, either a "yes" response to the dichotomous question or a "yes" response to any of the first three categories on the multiple choice question. The multiple choice format elicited a positive drinking response that was five percentage points higher (13.58% vs 8.47%; odds ratio 1.70, 95% confidence interval 1.15 to 2.51, p < 0.01). There were no differences among ethnic or racial groups.

Within the multiple choice question, responses indicating current drinking were as follows: cut back for pregnancy (61.6%), drink occasionally (93.0%), and drink regularly (0.01%). The channel of questioning, oral or written, did not produce significantly different levels of self-report (odds ratio 1.24, p < 0.28), and there was no interaction of format and channel.

Comment

Using a multiple choice question administered in either written or oral channels encouraged more disclosure of alcohol use by this population of pregnant women than did a dichotomous format. Although the study is limited by the absence of biologic confirmation of self-report, we believe these results reflect a true relative difference.

Why did the difference occur? For smoking, the response option that allows the woman to lessen the undesirability of smoking by saying that she has cut down in pregnancy accounted for 62% of the response among those indicating smoking. With drinking, this response was chosen infrequently. Occasional drinking was selected by 93% of the respondents who said they drank at all (vs 22% among smokers). This may correctly describe some or many of those selecting this response. It might also have been selected by binge drinkers and regular heavy drinkers who have not admitted to themselves the extent of their drinking or who are trying to make a plausible statement to decribe their drinking behavior.

Within the structure of this experiment, we cannot know, however, the absolute sensitivity of the question or which types of drinkers were captured in the increased disclosure rate. The true rate of drinking in the population may be closer to 25%. However, even moderate consumption may be of interest. Thus we recommend using the multiple choice question for screening only, ideally not as the exclusive method. The most useful follow-up questions may be direct probing of amount and alcohol-related problems. All pregnant women should be screened. Future research is needed on assessment techniques in pregnancy; more important, research is needed to develop interventions.

Human papillomavirus infection in women with multicentric squamous cell neoplasia

Anna Marie Beckmann, PhD, a.b Randy Acker, MS, Audrey E. Christiansen, BS, and Karen J. Sherman, PhDa, c

Seattle, Washington

Tissues from 32 women with multicentric squamous cell neoplasia of the anogenital region (72 anatomically distinct lesions at the cervix, vagina, vulva, perineum, or anus) were tested for the presence of human papillomavirus with the polymerase chain reaction or in situ hybridization. All the women had invasive carcinomas or grade 3 intraepithelial neoplasia lesions at a minimum of one site and one or two squamous cell lesions at another site(s). Human papillomavirus was detected in all of the multicentric lesions in 87.5% (28/32) of the women and in at least one lesion in 12.5% (4/32). In the 28 women with detectable human papillomavirus at all sites, 61% (17/28) had the same virus type(s) at all sites (types 6, 16, 6 and 16, 33) and 25% (7/28) had 6 or 16 at one site and both viruses at the other site(s). Four women (15%) had different virus patterns in the separate lesions. (AM J OBSTET GYNECOL 1991;165: 1431-7.)

Key words: Human papillomavirus, multicentric squamous cell neoplasia, polymerase chain reaction

Numerous studies have reported that infection with human papillomavirus (HPV) is associated with squamous cell neoplasia of the lower female genital tract. The strongest evidence implicating HPV infection in the pathogenesis of genital tract malignancies comes from investigations of human tissues with molecular hybridization techniques. Many such studies have demonstrated that most squamous cell intraepithelial neoplasias and invasive carcinomas of the cervix and vulva contain HPV deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). 1-3 Of the 60 HPV genotypes that have been identified by molecular analyses of human tissues, 22 have been found in anogenital lesions in both women and men.4 The spectrum of clinical conditions associated with HPV infection ranges from occult infections, where the viral DNA is present without cytologic or histologic evidence of infection, through condylomas to precancers and invasive carcinomas.2 HPV type 16 is the most common virus found in cervical squamous cell carcinomas and in high-grade intraepithelial lesions. 1-8 In contrast, HPV type 6 is found in the majority of vulvar, penile, and anal condylomas and is infrequently detected in high-grade intraepithelial lesions or invasive carcinomas.1.2 However, some studies have shown HPV type 6 to be present in vulvar squamous cell cancers.3 Other virus types (HPV types 18, 31, 33, 35, and 39) also are found in genital lesions but are less common than HPV types 16 and 6.1

The presence of HPV nucleic acids in squamous cell carcinomas of the cervix, vulva, vagina, and anus is consistent with a role for these viruses as etiologic agents in this morphologic type of anogenital cancer. The epidemiologic basis for considering cervical cancer as a sexually transmitted disease is well established.5 Recent epidemiologic studies have demonstrated that vulvar,6 vaginal,7 and anal8,9 cancers also have some similar risk factors with sexually transmitted diseases (number of sex partners, age at first intercourse, sexual practices). Although the proportion of squamous cell lesions that contain HPV is similar among these anatomic sites, the corresponding incidence of cancer varies markedly. In the United States the age-adjusted incidence of cervical cancer (8.0/100,000 in 1981 through 1985) is five to 10 times higher than that for carcinoma of the vulva (1.5), vagina (0.7), or anus (0.9) during the same time period.10 Also, the behavioral risk factors (number of sex partners, age at first intercourse, smoking history) for development of squamous cell carcinoma at each of these sites are somewhat different.5-9

In this study we have investigated this apparent differential pathogenicity of HPV infection in the female genital tract. We chose a study group of women with multicentric squamous cell neoplasia to determine if

M-Inv, Microinvasive squamous cell carcinoma; Inv, invasive squamous cell carcinoma; IN, intraepithelial neoplasia.

†HPV types in parentheses were determined from in situ hybridization analyses; Neg, negative; UK, unidentified type (not 6, 11, 16, 18, 31, 33, 35, 39, or 42).

infection with viruses of different oncogenic potentials (i.e., HPV type 6 or 16) was associated with individual squamous cell lesions at different epithelial surfaces in the female genital tract. Our objectives were (1) to determine if the same virus type was present in carcinoma in situ or invasive squamous cell carcinomas at different anogenital sites in the same individual and (2) to determine if different virus types were present in lesions of different malignant potentials at various epithelial surfaces in the same individual.

Material and methods

Subject tissues. Women were chosen for this study by surveys of pathology reports of individuals enrolled in case-control studies of cervical, vaginal, and vulvar cancer being conducted in western Washington State (principal investigator, Janet R. Daling, PhD). Women were eligible for inclusion if they had been diagnosed

with either invasive squamous cell cancer or grade 3 intraepithelial neoplasia at one site (cervix, vulva, or vagina) and had concurrent invasive cancer, grade 3 intraepithelial neoplasia, grade 1 or 2 intraepithelial neoplasia, or HPV-related morphologic changes in at least one other anogenital site (cervix, vulva, vagina, perineum, or anus).

The study group included 22 women with invasive cancer or grade 3 intraepithelial neoplasia at more than one site and 10 women with grade 3 intraepithelial neoplasia at one site and with lesions at other sites graded 1 or 2 intraepithelial neoplasia or HPV-related morphologic changes. These 32 women had lesions at 72 distinct anatomic sites (Table I) and were chosen for this study because paraffin-embedded fixed tissues were available from all of the lesions.

Histologic criteria. Anogenital squamous cell lesions were classified in three groups for this study: (1) in-

^{*}Primary lesion defined as that tumor for which patient was identified for case-control studies.

vasive or microinvasive squamous cell carcinoma, (2) cervical, vulvar, vaginal, or anal grade 3 intraepithelial neoplasia, and (3) other intraepithelial neoplasia lesions or morphologic changes indicative of HPV infection (condyloma or koilocytotic atypia at the cervix). Histopathologic diagnoses were determined from pathol-

Detection of HPV nucleic acids. The polymerase chain reaction was used to detect HPV DNA in 66 of the 72 lesions. Many of the lesions had already been analyzed by in situ hybridization before the development of the polymerase chain reaction method, and all of the available paraffin-embedded material had been used for in situ hybridization tests. Consequently, for this study adequate amounts of remaining tissue for polymerase chain reaction tests were not available for six of the 72 lesions, and in situ hybridization with asymmetric RNA probes was the only means for detection of HPV nucleic acids in these six lesions.

Polymerase chain reaction. Paraffin-embedded tissues were prepared for polymerase chain reaction analyses as described by Wright and Manos,11 and the polymerase chain reaction was performed on cellular DNA extracted from single 6 µm sections. Initially, tissue DNAs were amplified with oligonucleotide primers specific for the E6/E7 region of the HPV type 6 or 16 genomes.12 All positive results obtained with primers from the E6/E7 region were confirmed by amplification of a second region of the HPV type 6 or 16 genome; these were the El open reading frame (ORF) for HPV type 6 and the L1 ORF for HPV type 16. For the HPV type 6 E1 ORF, oligomer primers were GTTGCTGTG-GATGTGACAGCAACGT (nucleotides 699 to 723) and CCTGACCATCTCCCCCCATTTTCCGG (nucleotides 1321 to 1297). Both to confirm HPV 16 positive results and also to reanalyze tissue DNAs that initially tested negative by polymerase chain reaction with HPV type 6 or 16 E6/E7 primers, a set of degenerate consensus primers were used for the amplification reactions.18 These primers amplify a region of sequences common to at least 25 distinct genital HPV types,18 and, after RsaI digestion of amplification products, HPV types can be distinguished by the pattern of restriction enzyme fragments.13, 14

To assure maximum sensitivity and specificity of the polymerase chain reaction, all reaction products were electrophoresed through 4.0% agarose gels, transferred to nitrocellulose by Southern's method,15 and hybridized with type-specific or consensus probes derived from viral DNA sequences internal to the primer pairs. This approach for analysis of HPV genomes has been previously described by our group. 12, 14 For the HPV type 6 E1 ORF the probe sequence was AT-TATGCGACTGTGCAGGACCTAAAACGAAAGT-ATTTAGG (nucleotides 1055 through 1093); the probe sequences for the HPV types 6 and 16 E6/E7 ORF and the L1 consensus sequence have been described elsewhere.12,14 The amplification reactions allow consistent and reproducible detection of 0.1 pg of plasmid viral DNA after hybridization, representing about 10³ copies of the HPV genome.

In situ hybridization. In situ hybridization used asymmetric RNA probes from the E6/E7 region of the HPV types 6 or 16 genomes essentially as described by Stoler and Broker.16 Briefly, sections were dewaxed, digested with proteinase K (15 μg/ml), and acetylated (0.25% acetic anhydride in 0.1 mol/L triethanolamine, pH 8.0). Sections were hybridized overnight at 49° C, in stringent conditions, with 1.0 to 5.0×10^7 disintegrations/min of tritium-labeled HPV type 6 or 16 RNA. Antisense RNA probes (complementary to the messenger RNA made in vivo) were generated from HPV type 6 or 16 E6/E7 ORFs cloned into the transcription vector pSP6-T7-19 (Bethesda Research Laboratories, Inc., Gaithersburg, Md.). Hybridized sections were washed, dehydrated, coated with autoradiographic emulsion (Kodak NTB-2), and exposed for 4 weeks. Tissues were stained with hematoxylin for microscopic evaluation.

Results

Anatomic distribution of lesions. All 32 women in this study had two or three squamous cell lesions at various sites throughout the anogenital region; the site and histopathologic type of these neoplasias are detailed in Table I.

Lesions at the vulva and vagina (n = 10; age range 26 to 66; median, 57) were the most common in this study. Four of these women had grade 3 vulvar and vaginal intraepithelial neoplasia, five had grade 3 vulvar intraepithelial neoplasia and less severe vaginal lesions, and one had grade 3 vaginal intraepithelial neoplasia and a vulvar condyloma. Six women had lesions at the cervix and vulva (age range, 28 to 52; median, 38). Four of these women had invasive cancer or grade 3 intraepithelial neoplasia at both sites, and two had grade 3 vulvar intraepithelial neoplasia and less severe cervical lesions. Five women had lesions at the cervix and vagina (age range, 32 to 66; median, 60); all had either invasive cancer or grade 3 intraepithelial neoplasia at both sites. Two women had grade 3 intraepithelial neoplasia lesions at the vulva and anus (ages 36 and 40), and one women had grade 3 vulvar intraepithelial neoplasia and a distinct grade 3 intraepithelial neoplasia lesion on the perineum (age

Eight women had lesions at three sites. Three individuals had involvement at the cervix, vulva, and anus (ages 23, 26, 32); three had lesions at the vulva, vagina, and anus (ages 28, 41, 42); and two had lesions at the cervix, vagina, and vulva (ages 36, 69).

Although the numbers of women in each group outlined above are small, it appears that women with vag-

inal and either cervical or vulvar lesions were older than women with lesions involving the vulva and either the cervix or anus.

Detection of HPV nucleic acids. A total of 276 tissue blocks comprising 72 anatomically distinct lesions from 32 women were analyzed by polymerase chain reaction or in situ hybridization. Sixty-seven of the 72 lesions (93%) contained HPV DNA or RNA of types 6, 16, 33, 35, or unidentified HPV types (Tables I and II). HPV nucleic acids were more frequently detected in anal or perineal (100%; n = 9) and vulvar (96%; 26/27) lesions than in vaginal (90%; 18/20) or cervical (88%; 14/16) lesions (Table II).

When the histopathologic type of all lesions is considered, eight of nine (89%) condylomas contained detectable HPV DNA, six of six lesions (100%) graded 1 or 2 intraepithelial neoplasia were positive, 45 of 47 (96%) grade 3 intraepithelial neoplasia lesions were positive, and eight of 10 (80%) invasive cancers were positive (Table II). The negative condyloma was a flat lesion in the vagina of a woman with a grade 3 vaginal intraepithelial neoplasia lesion that contained HPV type 16 DNA. The two negative grade 3 intraepithelial neoplasia lesions were at the vulva and cervix of a woman who also had grade 3 vaginal intraepithelial neoplasia that contained HPV type 35 DNA. Of the two negative invasive cancers, one was a second primary cancer of the vagina in a woman with invasive cancer of the cervix that contained HPV type 35 DNA, and the second was an invasive cervical cancer in a woman with invasive vulvar cancer that contained HPV type 16 DNA. All of the HPV-negative tissues had been tested with the polymerase chain reaction; the less sensitive in situ hybridization method was not responsible for these negative results. Also, these tissues were tested with primer pairs for the human β -globin gene. ^{18, 17} All the HPV-negative lesions gave positive results with the β -globin primers (data not shown), demonstrating the adequacy of the DNA preparations for polymerase chain reaction analyses.

Distribution of HPV types by anatomic location of lesions. In the 67 lesions that contained detectable HPV nucleic acids, HPV type 6 or 16 was found in tissues from all anatomic sites, whereas HPV type 33 was seen only at the vulva, vagina, and anus, and HPV type 35 only at the cervix and vagina (Table II). HPV type 16 infection was more common at the cervix, vulva, and vagina than at the anus, whereas mixed infection with HPV types 6 and 16 was most common at the anus.

At all sites, as the degree of neoplasia increased, so did the proportion of HPV type 16-positive lesions (Table III). Double infections with HPV types 6 and 16 were approximately twice as common in noninvasive lesions; only one invasive cancer, at the cervix, contained both types 6 and 16 (Table II). HPV type 16 was the most common virus type found in invasive cancers or grade 3 intraepithelial neoplasia lesions of the cervix (5/11), vulva (14/24), or vagina (7/12). However, women with anal intraepithelial neoplasia were more likely to have a dual infection with HPV types 6 and 16 (4/5) than an infection with HPV type 16 alone (1/5) (Table II).

Virus patterns in multicentric lesions. HPV nucleic acids were detected in all of the anatomically distinct

Table III. HPV type-specific disease association in virus-positive multicentric lesions

IN, Intraepithelial neoplasia.

lesions in 87.5% (28/32) of the women in this study. Four women (subjects 2, 11, 15, and 23) had detectable HPV at only one site; three of these women had lesions at two sites and one had lesions at three sites (Table I).

The proportion of women with HPV DNA or RNA at all sites was not dependent on whether lesions were present at two or three sites (87.5% positive in both groups; 21/24 and 7/8, respectively). In women with lesions at two sites, the proportion of individuals with HPV at both sites did not depend on the degree of neoplasia. For women with grade 3 intraepithelial neoplasia at two sites, 87.5% (14/16) were positive at both sites. For women with grade 3 intraepithelial neoplasia at one site and less severe neoplasia at the other involved site, 87.5% (7/8) were positive at all three sites. In women with lesions at three sites, HPV was found in five of six individuals (84%) with grade 3 intraepithelial neoplasia at all sites and in both women with one grade 3 intraepithelial neoplasia lesion and less severe neoplasia at the other two sites.

In the 28 women with detectable HPV at all sites, 61% (17/28) had the same virus type(s) at all sites and 25% (7/28) had HPV type 6 or 16 at one site and both viruses at the other site(s) (Table I). Four women (14%) had different virus patterns in the separate lesions (subjects 6, 10, 12, and 18; Table I).

Occurrence of double HPV infections. Thirteen of the 32 women (41%) with multicentric neoplasia and 22 of the 72 lesions (31%) showed evidence of infection with HPV types 6 and 16. Six of the 32 women (19%) were infected with HPV type 6 and 16 at more than one site, and seven of 32 (22%) were infected with both types at only one site.

The total proportion of women with both HPV type 6 and 16 infections was identical in those individuals with grade 3 intraepithelial neoplasia at multiple sites (41%, 9/22) and those with grade 3 intraepithelial neoplasia at one site and lesions less than grade 3 intraepithelial neoplasia at other sites (40%, 4/10). In the first group of women, four of 22 (18%) individuals had double infections at more than one site, and five of 22 (23%) had double infections at only one site. In the second group, two of 10 women (20%) had double infections at more than one site and the same proportion had double infections at only one site.

Comment

In this study of women with multicentric squamous cell neoplasia of the lower genital tract, all of the 32 women had molecular evidence of HPV infection at at least one site. Five lesions from four individuals lacked detectable HPV nucleic acids; in each instance either an invasive cancer or grade 3 intraepithelial neoplasia at another site was HPV positive. Failure to detect HPV DNA in genital squamous cell carcinomas by conventional hybridization techniques (i.e., Southern, dot blot, in situ) may reflect a sampling error (missing the lesion), the presence of small amounts of virus that would not be detected by the methods used, the presence of a virus type unrelated to the probes, or the absence of HPV in the tumor. In this study the lack of HPV in these lesions is unlikely to represent a sampling error as sections from the entire tumor were analyzed in all cases. The sensitivity of the polymerase chain reaction is such that viral DNA should be detectable if present; however, the late consensus primers may not detect all HPV types that can infect the genital tract. A more convincing explanation for these negative findings is that random nicks introduced into the viral DNA after storage of paraffin tissues removed the oligonucleotide primer binding sites. Other investigators have demonstrated random loss of amplification ability of the human β-globin gene, which increases with the age of the paraffin-embedded tissue.¹⁷ Alternately, the HPVnegative lesions may not contain any viral nucleic acids.

Lower rates of HPV positivity than what was found in this study have been reported in previous studies of women with multicentric squamous cell genital lesions. Pilotti et al.18 used in situ hybridization to study tissues from women with multicentric disease and found that 73% (19/26) were positive for HPV DNA. These women were selected by clinical observation of vulvar wart-like lesions and simultaneous lesions at other sites, and approximately one half of the women had grade 3 vulvar intraepithelial neoplasia and the other 1436 Beckmann et al.

November 1991

Am | Obstet Gynecol

half had condylomatous vulvar lesions. Bergeron et al. 19 found HPV DNA by Southern hybridization in 87.5% (21/24) of women with multiple condylomatous lesions of the anogenital region. Kulski et al.20 found evidence of HPV infection in 85% (109/128) of women with cervical abnormalities who also had vulvar tissues collected for analysis by filter in situ hybridization. The 100% patient positivity rate in this study is, most likely, a result of the use of polymerase chain reaction, a test that is many times more sensitive than other detection methods. However, when considering each lesion separately, we found lower rates of HPV detection in the cervices of affected individuals than were seen at other sites in the genital tract. These results are similar to those of Reid et al.,21 who found detection rates, in cervical and vulvar biopsy specimens that showed koilocytotic atypia or neoplasia, of 86% and 93%, respectively. Conceivably, a wider variety of HPV types infect the cervix than the vulva, and these types infecting the cervix are not detectable under our experimental conditions.

The relative frequencies of vulvar, cervical, vaginal, or anal HPV infections occurring simultaneously, in any combination, are not known. Some studies have shown that in women with vulvar condyloma or grade 3 vulvar intraepithelial neoplasia up to 60% also have cervical HPV infections or preneoplastic lesions. 22-24 Conversely, in women diagnosed with HPV-related cervical lesions, more than one half also have vulvar lesions.20 In 1984, Okagaki25 proposed the term genital neoplasm papilloma syndrome to describe this clinical observation of synchronously or metachronously occurring multiple HPV infections or HPV-associated intraepithelial neoplasia lesions in the female genital tract. Also, epidemiologic studies have shown a significant association between the simultaneous detection or occurrence of cervical and vulvar cancers and squamous cell cancers at other anogenital sites,26,27 implicating a common etiologic agent.

The patterns of viral distribution in the multicentric lesions examined in this study suggest that the majority of these neoplasias were the result of diffuse HPV infection. Four women had different HPV types found in different areas of the genital tract; of these, two had two lesions of the same histologic grade (grade 3 vulvar intraepithelial neoplasia and grade 3 vaginal intraepithelial neoplasia or grade 3 cervical intraepithelial neoplasia), and the other two had grade 3 vaginal intraepithelial neoplasia and a vulvar condyloma, or grade 3 cervical intraepithelial neoplasia, vulvar invasive cancer, and an anal condyloma. Our results are consistent with the idea that squamous cell malignancies of the lower female genital tract share a common etiology, of which one factor is HPV infection.

Women with multicentric HPV infection, whether in-

volving benign condylomas, precancers, or invasive lesions, appear to have much higher rates of multiple infections than do groups of women with only singlesite involvement. In this study 13 of the 32 (41%) women had mixed infections throughout the lower genital tract, and 22 of the 72 (31%) individual lesions contained both HPV types 6 and 16 DNA. These results agree with other studies in which from 38% to 100% of women with multicentric lesions were infected with two or more HPV types. 18-20, 28 In contrast, studies of women with only cervical or vulvar lesions have shown low rates (<5%) of multiple HPV infections.2 This study did not analyze the exact cellular location of each virus type present in a single lesion. Reid et al.21 have shown that in individuals with multiple HPV infections the different virus types were localized in demarcated areas of differing histopathologic appearances. However, in our study most all of these lesions containing HPV types 6 and 16 DNA were of similar or identical histopathologic grades. The observation of multiple infections in women with synchronously occurring multicentric lesions suggests that this study group represents a selection of individuals in whom the effectiveness of the host response to HPV infection is inadequate.

In this study different viruses infecting differing areas of the female genital tract were ruled out as a potential explanation for the observed variation in the occurrence of squamous cell cancers at the cervix, vulvaa, vagina, and anus. HPV type 16 infection was the common thread among intraepithelial neoplasia III or invasive lesions at all sites. Interestingly, simultaneous infections with HPV types 6 and 16 were more common at the vulva and perineal and perianal skin than at the cervix, perhaps indicating a site restriction of HPV type 6 infection to cutaneous epithelium. In any event, factors other than the infecting virus type appear to be responsible for the 15-fold increase of cervical cancer over cancers at the vulva or vagina or anus. The unique properties of the cervical transformation zone²⁹ may make it more susceptible to HPV-induced oncogenesis than the native squamous epithelium is elsewhere in the lower genital tract. We are currently investigating the hypothesis that the cervix is more likely to undergo malignant changes after HPV infection than is the vulva, vagina, or anus because of site-specific variations in the expression of the HPV transforming genes E6 and E7.

We thank Drs. James McDougall and Denise Galloway for helpful and critical consultation.

Human T-cell lymphotropic virus type I infection and pregnancy: A case-control study and 12-month follow-up of 135 women and their infants

Yves Ville, MD,^{a, b} Eric Delaporte, MD,^{a, c} Martine Peeters, PhD,^{a, c} Marianne Leruez, MD,^a Eric Glowaczower, MD,^a and Hervé Fernandez, MD^b

Franceville, Gabon, and Clamart and Paris, France

Human T-cell lymphotropic virus type I (HTLV-I) infection is common in Gabon, but its influence on pregnancy is unknown. A single case of acute T-cell leukemia in a pregnant woman has been reported in the literature, but, as far as we know, we present the first case-control study analyzing the relationship between HTLV-I seropositivity and the course and outcome of pregnancy. The study concerned 45 HTLV-I seropositive pregnant women matched with 90 seronegative pregnant women. None has clinical features of HTLV-I infection during pregnancy or during the year after delivery. HTLV-I seropositivity did not significantly affect the course or outcome of pregnancy. After losing maternal antibodies to HTLV-I, none of the infants had seroconversion to HTLV-I 1 year after birth. Filaria infection was correlated with HTLV-I seropositivity, but confounding factors may account for this observation. (AM J OBSTET GYNECOL 1991;165:1438-43.)

Key words: Africa, controlled study, HTLV-I, pregnancy, transmission, filaria infection

Human T-cell lymphotropic virus type I (HTLV-I) is a retrovirus that has been associated with two clinical entities, adult T-cell leukemia-lymphoma¹ and a neuromyelopathy (TSPP).² HTLV-I is mainly endemic in southern Japan, Equatorial Africa, and the Caribbean islands. The prevalence of antibodies is higher in women than in men of comparable age. The virus can be transmitted through sexual contact, intravenous drug abuse, breast milk, and blood transfusions.³ On the basis of seroepidemiologic studies of Japanese populations in endemic districts, >98% of seropositive subjects show no evidence of disease, and the cumulative lifetime risk of adult T-cell leukemia-lymphoma in those infected before age 20 is estimated at 4%.⁴

Recently, serologic studies have shown that HTLV-I is not restricted to endemic areas. In New York City and New Orleans, 24% of intravenous drug abusers have antibodies to HTLV-I.5 Among blood donors in the United States, HTLV-I seroprevalence (0.04%) is three times higher than the human immunodeficiency

virus seroprevalence.⁶ In Paris, the seroprevalence rate is 0.6% among pregnant women.⁷ Although the effect of another retrovirus, human immunodeficiency virus, has been widely studied in pregnant women, little is known concerning HTLV-I and pregnancy. To our knowledge, only Ohba et al.⁸ have reported a case of HTLV-I—associated adult T-cell leukemia-lymphoma in a young pregnant Japanese woman.

To determine the influence of HTLV-I infection on the course and outcome of pregnancy, we conducted a case-control study of pregnant women living in an area of high HTLV-I seroprevalence and monitored the mothers and children for 1 year after delivery. The study was performed in Gabon, western Equatorial Africa, where we have previously found HTLV-I seroprevalence rates ranging from 5.0% in urban areas to 10.5% in rural areas among the general adult population.⁹

Patients and methods

Patients. The study was carried out at the general hospital in Franceville, Gabon, where most pregnant women in the Haut-ogoue province are monitored and give birth. The southern province of Gabon is mainly a rural area with 170,000 inhabitants and the capital, Franceville, counts 30,000 inhabitants. It is a transition zone between equatorial rain forest and savannah. Two main ethnic groups are represented, one originating from the savannah (group K), the other from the forest (group B). These two groups are equally represented in Franceville but live in different parts of the town,

where environmental factors, in particular, exposure to insect vectors are similar.

In Franceville the overall HTLV-I seroprevalence rate among pregnant women is estimated at 10.5%.9 In other studies we have shown that HTLV-I seroprevalence rates increase with age and that the rate is four times higher among people from the forest than among people from the savannah.9 Seroprevalence rates are similar in people of the same ethnic group living in different parts of the town but different between people of different ethnic groups.9

Between 1986 and 1988 we screened pregnant women attending the maternity unit of Franceville, after obtaining informed oral consent from them. To optimize follow-up we studied only women living in Franceville. Each seropositive pregnant woman was matched for age and ethnic group with two seronegative women attending the unit for the first time on the same day as or the day after the seropositive women. The women selected lived in Franceville and only women of the lower socioeconomic class come to the general hospital, therefore the cases and controls were probably representative of a relatively homogeneous population. The clinical examination was performed by a physician, once during the pregnancy, at delivery, and once a year later.

The following parameters were studied: (1) obstetric history, assessed in terms of gravidity and parity and the number of living and dead infants; (2) sexual activity of these women and their risk of exposure to sexually transmitted disease, assessed in terms of the cumulative number of sexual partners, contraception, history of sexually transmitted disease, active syphilis, genital erosions, and abortions¹⁰; (3) clinical workup for adult T-cell leukemia-lymphoma, including investigations of lymphadenopathy, hepatosplenomegaly above type II, and skin lesions such as erythroderma and nodule formation, and clinical tropical spastic paraparesis including investigation of spastic gait or frantic paraplegia, low back pain, spasticity and hyperreflexia of the legs and arms, extensor plantar responses, spastic bladder, and severe constipation; (4) course of pregnancy, assessed in terms of four main complications (malaria, latent syphilis serologic results, pregnancyinduced hypertension, preterm delivery) that are not logically related to viral infection but are well-known causes of maternal and fetal morbidity; and (5) outcome of pregnancy, assessed in terms of gestational age and mode of delivery. Unfortunately, women in Gabon come to the hospital in the second part of labor and it is impossible to determine the time of membrane rupture.

The infants were examined at birth, at 6 months, and at 1 year. The Apgar score at 1 minute, fetal weight, color of amniotic fluid and gross placental aspect were

used to assess fetal outcome; no other signs of fetal distress could be investigated. Blood tests for malaria and filaria, serologic tests for HTLV-I, differential blood cell counts, and cytologic examinations were routinely performed during the first visit of the pregnant women. At delivery and 1 year later, a blood sample for HTLV-I serologic testing was obtained from the women. Blood for HTLV-I serologic testing was also taken from the infants at birth, at 6 months, and at 1 year.

Laboratory and statistical methods

HTLV-I serology. Sera were tested for immunoglobulin G antibodies to HTLV-I by means of enzymelinked immunosorbent assay (ELISA) (Dupont de Nemours, Wilmington, Del.); ELISA-positive sera were retested by means of Western blot test for confirmation (Dupont de Nemours). A Western blot assay was considered positive when it showed antibodies to at least two gene products (p 19 or p24 for gag antigens and gp46 for the envelope antigen).11 A Western blot showing antibodies to only gag antigens was considered indeterminate, and such women were excluded from the study, as were those with positive ELISA and negative Western blot. Thus 11 pregnant women found to be ELISA positive and Western blot indeterminate for HTLV-I and two women who were ELISA positive and Western blot negative for HTLV-I were excluded from the study.

Syphilis serology. Sera were screened with a semiquantitative method (VDRL, Diagnostics Pasteur, Marnes la Coquette, France); positive sera were confirmed by means of *Treponema pallidum* hemagglutination assay (Behring Diagnostics). A test was considered positive if the titer was ≥1/80.

Blood parasites. Malaria (Plasmodium falciparum) and filaria, both endemic in Gabon (Loa-loa, Dipetalonema perstans), were diagnosed by thick-staining of blood smears in Giemsa.

Significance tests were based on the Student t test and χ^2 analysis with or without Yates' correction, depending on whether the expected values were >5 or between 3 and 5, for the likelihood ratio statistic and 95% confidence intervals estimates and normal approximation.

Results

Among the 48 seropositive pregnant women selected, 45 were seen at delivery and 40 1 year after delivery. Among the controls, 90 were seen at delivery and 77 1 year later. Among the cases, 38 of 45 were from ethnic group K, five of 45 from group B, and two of 45 from other ethnic groups; this distribution was similar to the ethnic distribution seen in the control group (Table I). All cases and controls were living in the Franceville area; in wooden houses (only the upper class have brick

*Peripheral blood cell count could be obtained both at midtrimester and 1 year after delivery for 40 cases and 77 controls.

houses). As shown in Table I, no difference between the cases and controls was observed regarding age or sexual and obstetric history. In spite of the high proportion with a past history of sexually transmitted disease, none of the cases or controls showed genital ulcerations or neurologic diseases throughout the study period.

No clinical manifestations of HTLV-I infection were found during pregnancy or 1 year after delivery. The hematologic profile was similar in the two groups at the first visit and 1 year after delivery (Table II). No HTLV-I seroconversion occurred in the control group and the Western blot pattern of all the subjects remained unchanged throughout the study.

The course and outcome of pregnancy and the fetal outcome are shown in Table III. The case group showed only slightly higher rates of preterm delivery and complicated pregnancy when compared with those of controls, but these differences were not significant

and the mean duration of pregnancy was the same in both groups.

The systematic search for parasites in the blood showed no difference between cases and controls with regard to P. falciparum; in contrast, the incidence of filaria parasites was significantly higher in the case group (46%) than in the controls (25%) (p, 0.02; χ^2 , 6.51) (Table IV). Similar results were found in ethnic groups K and B (Table V). Pregnancy outcome was not affected by parasitemia or ethnic distributions. Blood parasites were not sought in the adults 1 year after delivery.

Forty-four children of the seropositive women and 84 children of the control mothers were examined at 6 months and at 1 year of life and were clinically healthy. All the women breast-fed for ≥3 months, with the exception of one woman in the control group who weaned her baby after 3 weeks. The HTLV-I serologic status of the infants born to HTLV-I-seropositive

women was analyzed by means of Western blot. At birth, the infants showed the same Western blot pattern as their mothers, while at 6 months 35 of 44 (79.5%) infants were seronegative and nine (20.5%) still had antibodies to the gag gene products but not the env gene products. At 1 year of age, all the infants were seronegative in the ELISA and Western blot (as in the control group) and no Western blots were indeterminate. These findings reflect the gradual lost of maternal anti-HTLV-I immunoglobulin G.

Comment

Among the 45 HTLV-I-seropositive women studied, 38 (84.4%) were from tribes of the equatorial forest and 5 of 45 (11.1%) from tribes of the savannah. The higher seroprevalence rate among people living in the tropical rain forest have previously been described in Gabon⁹ and Zaire¹² and has been confirmed by the finding of clusters of TSP in the tropical forests of Zaire13 and Gabon.14

Pregnancy normally affects cellular immune status, with a decrease in the number of helper T lymphocytes and sometimes an increase in the number of suppressor T lymphocytes. Pregnancy may thus cause a further decline in an immune system already compromised by retroviral infection and vice versa.15 The effect of the human immunodeficiency virus on the course and outcome of pregnancy remains controversial.16

To our knowledge, the only described case of adult T-cell leukemia in pregnancy was reported by Ohba et al.8 in 1988, in a 28-year-old Japanese woman at 38 weeks' gestation. The infant recovered and remained

free of HTLV-I infection after 3 months of life, but the mother died 6 months after delivery. In our prospective study of 45 pregnant women who seropositive for HTLV-I, none presented clinical features of HTLV-I infection either during pregnancy or in the year after delivery. Both the seropositive women and seronegative controls showed numerous anomalies in the peripheral blood cell count, including anemia, neutropenia, and eosinophilia, characteristic of communities exposed to intermittent viral and bacterial infections; chronic helminthic infection; and recurrent malaria.

However, no hematologic changes characteristic of HTLV-I infection were found, in particular rosette-like lymphocyte nuclei; the eosinophilia observed was not correlated with HTLV-I infection and is presumed to be a response to chronic helminthic infections. No conclusions can be drawn concerning the influence of pregnancy on HTLV-I infection, because we did not study a nonpregnant infected group and markers of immune status were not included in the analysis. As the onset of acute adult T-cell leukemia-lymphoma during pregnancy is rare and HTLV-I infection is a long-term condition in which the majority of the population remain asymptomatic for many years, a survey of a larger population may lead to different conclusions.

The course and outcome of pregnancy were not significantly influenced by the seropositivity of the mother, but the cases did tend to have a higher rate of preterm delivery and complicated pregnancy than controls. The lack of statistical significance could be due to the small sample size.

Although the transmission of HTLV-I has been discussed by several authors, ¹⁷⁻¹⁹ mainly in Japan, data are lacking in Africa. The main route of transmission seems to be mother to child, as suggested by familial clustering ¹⁷ and surveys of seropositive mothers and their children. ¹⁸ Geographic and familial clustering of HTLV-I is also common in Gabon. The vertical route of transmission is naturally limited to three possible modes: transplacental, intrapartum, and through the maternal milk. ^{19, 20} As HTLV-I is not endogenous, ge-

netic transmission is unlikely. A follow-up study of the mothers and their infants is in progress. After 1 year, none of the children we examined had undergone seroconversion to HTLV-I, suggesting that there was no intrauterine infection. However, a longer follow-up of these children and their siblings is needed to evaluate mother-to-child transmisson, including transmission through milk, because serconversion usually occurs beyond the first year of life.²⁰

Mother-to-child transmission is estimated to occur in approximately 20% of breast-fed children and 1% to 4% of bottle-fed infants in Japan, although results are not uniform. In Japan, seroconversion occurs in 25% of the children of seropositive mothers after 3 years of life 19, 20 and in 50% of children if they are breast-fed, 20 even if only for a short period. By contrast preliminary results from a study in Haiti²¹ indicate that only 12% of infants have had seroconversion by the age of 18 to 34 months. It will be interesting to compare the results from Japan and Haiti with those of our cohort. Further investigations are necessary to evaluate what factors could influence the relative importance of this mode of transmission.

Although transmission can occur by the transfusion of infected blood products, no history of transfusion was found in either group of subjects we studied.

Sexual transmission has been incriminated by several authors. ^{22, 23} In Japan, HTLV-I seroprevalence is higher in women >30 than in men of the same age, suggesting that transmission occurs predominantly from the man to the woman. ^{3, 22} In Gabon, where prevalence increases with age but is sex independent, ⁹ syphilitic serologic results, the number of sexual partners, and the number of abortions adjusted for age are good indicators of sexual activity, because contraception is uncommon and the prevalence of sexually transmitted disease is high. ¹⁰

In our study sexual transmission did not seem to be a major route. In a recent study of female prostitutes in Kinshasa, Zaire,¹³ no association between HTLV-I seropositivity and the number of partners was observed, as in our study, suggesting that sexual trans-

mission of HTLV-I is less efficient than sexual transmission in HIV-1 infection. Nevertheless, that study showed that prostitution is a risk factor and that sexual transmission of the virus does occur. In Jamaica, women with a high cumulative number of sex partners and serologic evidence of syphilis were more likely to be HTLV-I seropositive.²³

The involvement of arthropods in the transmission of HTLV-I has been suggested²⁴ but remains controversial²⁵; in our study the rate of filaria infection was significantly higher in the HTLV-I-seropositive group than in the controls, but this finding must be interpreted with caution. Indeed, although the women in both groups lived in Franceville in a similar environment, their relative exposure to insect vectors may be different when they visit their village of origin.

In conclusion, HTLV-I seropositivity in pregnant women did not affect the course or outcome of pregnancy in comparison with a noninfected control group. There was no evidence of mother-to-child transmission at 12 months of infant life, although follow-up of this cohort is continuing. HTLV-I infection and filaria infection were correlated, but this may be due to confounding factors that were not investigated here.

Detection of *Chlamydia trachomatis* endocervical infection in asymptomatic and symptomatic women: Comparison of deoxribonucleic acid probe test with tissue culture

Lisa I. Yang, MD, Elizabeth S. Panke, MD, PhD, Phyllis A. Leist, PhD, Richard J. Fry, MD, and Richard F. Lee, PhD

Cincinnati, Ohio

A deoxyribonucleic acid probe assay (PACE 2, Gen-Probe, San Diego) was compared with a standard tissue culture method for detection of *Chlamydia trachomatis* endocervical infection in both asymptomatic and symptomatic women. The results of the probe test were expressed as a ratio of relative light units of the specimen per relative light units of the cutoff recommended by the manufacturer. Samples with sample/cutoff ratios near 1.0 were repeated until two or more consistent ratios were obtained. A total of 426 specimens were obtained, with an overall disease prevalence of 10.1%. Of the 426 specimens examined, seven (1.6%) were near the cutoff and were retested. The results of 426 samples with matching cultures indicated that the manufacturer's discrete cutoff was adequate for results determination. The deoxyribonucleic acid probe test was essentially equivalent to standard tissue culture in terms of sensitivity, specificity, and positive and negative predictive values in a low-prevalence patient population. (AM J OBSTET GYNECOL 1991;165:1444-53.)

Key words: Chlamydia trachomatis, deoxyribonucleic acid probe, tissue culture

Infection by *Chlamydia trachomatis* is recognized as the most prevalent sexually transmitted disease worldwide, with an estimated four million cases per year in the United States,^{1, 2} While *C. trachomatis* is an important pathogen in lower and upper genital tract infections and pregnancy complications, a substantial number of cases occur without symptoms in patients.^{1, 3, 4} The most important factor in controlling the chlamydia epidemic is correct and timely diagnosis. This has previously been limited to cell culture, which is considered the gold standard in spite of <100% sensitivity. New techniques include antigen detection with enzyme immunoassay, direct fluorescent antibody, and deoxyribonucleic acid (DNA) probe tests.

PACE 2 (Gen-Probe, San Diego) is a commercially available, rapid detection test for *C. trachomatis* endocervical and urethral infection. The PACE 2 system uses the technique of nucleic acid hybridization to identify *C. trachomatis* DNA directly from urogenital swab specimens. Nucleic acid hybridization tests are based on the

ability of complementary nucleic acid strands to specifically align and form stable double-stranded complexes. PACE 2 uses a single-stranded DNA probe labeled with a chemiluminescent marker. The probe is complementary to ribosomal ribonucleic acid (rRNA) of the target organism. If rRNA from C. trachomatis is present in a collected specimen, the labeled DNA probe combines with it to form a stable DNA/RNA hybrid. Magnetic spheres are added to the reaction and these bind only to the stable hybrids. The labeled hybrids are magnetically separated from the nonhybridized probe and measured in a luminometer. A greater light response is generated with increasing numbers of stable hybrids present in the specimen (Fig. 1). The luminometer and magnetic separation unit are the only specialized laboratory equipment needed to perform this test. The reagents are commercially available from Gen-Probe. Other materials required include water bath, vortex mixer, micropipettes, and pipettes that are routinely available in most clinical laboratories.

The purpose of this study was to compare a new DNA probe assay format, designed to increase sensitivity and simplify procedural steps, with a standard cell culture method for the detection of *C. trachomatis* in endocervical swab specimens in both asymptomatic and symptomatic women seen for obstetric and gynecologic care. Currently, chlamydia infection may remain undiagnosed, misdiagnosed, or empirically treated with antibiotics because the standard diagnostic test, namely, cell culture, remains unavailable in smaller hospitals, is

labor intensive, and requires a lengthy turnaround time. The development of a reliable, rapid, and easyto-use laboratory test for the detection of chlamydial infection has important ramifications for patients and clinicians. We also evaluated whether the discrete manufacturer-recommended cutoff value is sufficient for unequivocal reporting of results for all patient specimens.

Methods

ţ

Patient population. Patients in the study were divided into two groups. Group 1 consisted of asymptomatic pregnant women who were seen for prenatal care. Patient charts were reviewed to determine the presence or absence of symptoms related to chlamydial infection at the time of specimen collection. Group 2 consisted of women seen for gynecologic care with symptoms of lower genital tract infection (i.e., vaginal discharge, pelvic pain, dyspareunia, coexisting sexually transmitted disease), patients requesting cultures because of known sexually transmitted disease exposure, and pregnant women with symptoms. Patients receiving antibiotics (duration, ≤4 weeks) before specimen collecton and individuals with no clinical histories were excluded from the study. All patients were seen at Good Samaritan Hospital Outpatient Clinic or Group Health Associates, Cincinnati, between September 1989 and June 1990.

Specimen collection. The exocervix was first cleansed of excess mucus with a Dacron swab. Subsequently, two endocervical specimens were obtained, one for DNA probe test and one for C. trachomatis culture. The samples were collected in no designated order, and

collection was not randomized. However, collection was done by 17 different physicians, thus avoiding systematic collection bias. Specimens collected for DNA probe test were placed in Gen-Probe transport tubes containing 1.0 ml of specimen preservative and glass beads. Samples were stored at room temperature for up to 1 week before being tested. For culture, specimens were placed in chlamydia transport media (2-sucrose-phosphate media, Bartel's Immunodiagnostic Supplies, Bellevue, Wash.) and processed immediately or stored at 4° C for no longer than 24 hours.

DNA probe assay. The Gen-Probe PACE 2 system chemiluminescent-labeled DNA probe test was used in the study. This system uses an acridinium-ester-labeled single-stranded DNA probe that is complementary to ribosomal rRNA of C. trachomatis.5

All reagents and samples were brought to room temperature before assay. Each sample was mixed in a vortex for 10 to 15 seconds. Swabs were then expressed of liquid on the side of the tube and discarded. Reconstituted probe reagent (100 µl) was pipetted into each tube. Specimens were mixed in a vortex, and then 100 µl of sample was added to the probe. The tubes were covered with a sealing card and the tube rack was shaken three to five times to mix. The mixture was incubated at 60° ± 1° C water bath for 1 hour. One milliliter of separation solution was added to each tube and then incubated at 60° ± 1° C for 10 minutes. The separation rack was placed onto a magnetic base at room temperature for 5 minutes.

The supernatant was decanted and the tubes blotted on absorbent paper. Each tube was filled to the rim with wash solution. The tubes remained on the separation

1446 Yang et al.

rack for 20 minutes at room temperature The supernatant was then decanted but not blotted. The tube rack was shaken to resuspend the pellets. For each set of specimen runs, three negative controls and one positive control were simultaneously processed.

The tubes were read on the Leader I luminometer (Gen-Probe) with the chlamydia protocol selected. The results of the test were calculated based on the difference between the response relative light units (RLU) of the specimen and the mean relative light units of the three negative references.

Culture. Specimens were mixed in a vortex with sterile glass beads for 60 seconds, and debris was removed by centrifugation at 900 g for 5 minutes. Supernatant (200 µl) was inoculated into each of two shell vials containing McCoy cell monolayers on coverslips (Bartel's Immunodiagnostic Supplies, Bellevue, Wash.). Vials were centrifuged for 1 hour at 3000 g at 25° C. Supernatant was aspirated, and 1.0 ml of chlamydia culture media with cycloheximide was added to the monolayers. Vials were incubated at 35° C for 48 hours. The coverslip from one vial was fixed in chilled acetone and stained with fluorescein-labeled antichlamydial mouse monoclonal antibody reagent (Bartel's). Coverslips were examined at a magnification of ×100 and inclusions were confirmed at ×400 with an Olympus fluorescent microscope. A culture was considered positive if one or more inclusions were present. Passage of the second vial was performed on questionable one-vial results, monolayers showing elementary bodies but no inclusions, toxic reactions, or any specimen with discrepant probe and culture results.

Discrepant results. All specimens were stored at -70° C for further reference if discrepant results occurred. When discrepant results were obtained, specimens were submitted in blind fashion to Gen-Probe for analysis by probe competition assays. The samples were tested with the PACE 2 assay format with halfvolume reactions (50 μl sample and 50 μl probe). Three separate assays were performed for each specimen: (1) sample and labeled C. trachomatis probe, (2) sample and labeled C. trachomatis probe and ×100 unlabeled homologous probe (C. trachomatis), and (3) sample and labeled C. trachomatis probe and ×100 unlabeled heterologous probe (Mycoplasma pneumoniae). A 90% reduction in difference expressed in relative light units (competition) in tube No. 2 versus tubes No. 1 and No. 3 indicated that a specific hybridization reaction took place and that C. trachomatis nucleic acids were present in the sample. A reduction <90% indicated that a specific hybridization reaction had not taken place (no competition) and that C. trachomatis nucleic acids were not present in the sample (Fig. 2). In addition, DNA probe assays were performed on all specimens submitted for culture when culture was positive and DNA probe assay was negative.

Cutoff range for the DNA probe assay. The results of the DNA probe test were calculated on the basis of the difference between the response in relative light units of the specimen and the mean of three negative reference values. According to the manufacturer, the specimen should be considered positive for C. trachomatis if the difference between the specimen response and the mean of the negative reference is ≥ 300 RLU. One of the objectives of the study was to determine if using such a discrete manufacturer recommended cutoff value is sufficient for unequivocal reporting of results for all patient samples. This question is especially important for patient samples that may have values in relative light units that are close to the recommended cutoff value. Therefore we obtained interassay precision data for samples at various levels from the cutoff value, examined the distribution of values in relative light units for all patient samples in relation to the cutoff value, and correlated the DNA probe test results with those of tissue culture and clinical data. All patient values in relative light units were expressed as a ratio of the sample relative light units to the cutoff relative light units recommended by the manufacturer. Ratios ≥1.0 represented patient specimens that were positive for C. trachomatis (i.e., difference ≥ 300 RLU). Ratios <1.0 represented patient specimens that were negative for C. trachomatis (i.e., difference <300 RLU). Additionally, more decisive negative or positive results were obtained the further a given ratio deviated from the value of 1.0. Specimens with ratios near 1.0 were multiply tested to determine if a cutoff range rather than a discrete cutoff point could be determined for more accurate results.

Statistics. Nonparametric comparisons of categoric variables used χ^2 analysis. Calculations for test validity were made with standard formulas for sensitivity, specificity, and predictive values.

Results

A total of 426 endocervical specimens were evaluated by tissue culture and by the Gen-Probe PACE 2 DNA probe assay. An additional 2703 patient specimens without matching cultures were analyzed by DNA probe only. These additional samples were used to obtain more precise analysis of borderline specimens and to verify the distribution of study samples around the cutoff.

Interassay precision data. Table I shows betweenrun precision data for the DNA probe assay for matched and unmatched specimens. This interassay precision data was calculated by assaying selected samples in several consecutive runs. A negative control sample, a positive control sample, and several patient samples with various sample/cutoff ratios were evaluated. The coefficient of variation for the negative control samples was approximately 28%, whereas the coeffi-

7

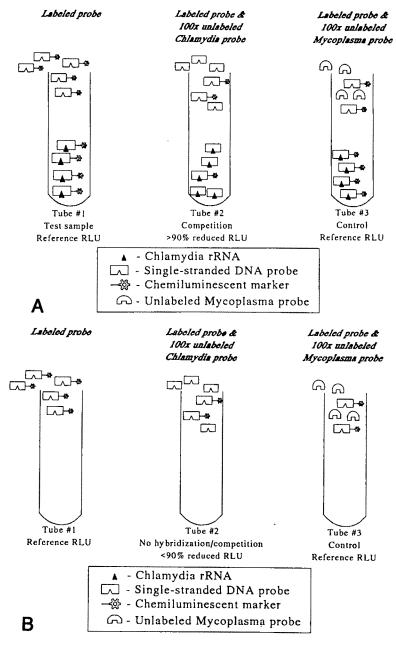

Fig. 2. Probe competition assay. A, Positive reaction occurred when >90% reduction in difference in relative light units was detected in tube No. 2 compared with tubes No. 1 and No. 3. When C. trachomatis nucleic acids were present in the sample, competition reaction occurred in tube No. 2. B, Negative reaction occurred when <90% reduction in difference in relative light units was detected in tube No. 2 compared with tubes No. 1 and No. 3. No competition reaction occurred in tube No. 2.

cient of variation for the positive control samples was approximately 16%. The coefficients of variation for the patient samples were as high as 23%. With such interassay variation of up to 30%, occasional patient samples that were truly positive for C. trachomatis could, on a single run, have a ratio as low as 0.7. Patient samples near the cutoff value (ratio 1.0) were assayed several times to ascertain whether DNA probe retesting of those samples allowed for consistent and clinically relevant results. Samples were considered negative for

C. trachomatis by the DNA probe assay if results were consistently < 1.0 (i.e., $0.7 \le \text{ratio} < 1.0$) or a single ratio ≥ 1.0 (i.e., $3.0 > \text{ratio} \geq 1.0$) occurred among other results < 1.0. Samples were considered positive for C. trachomatis by the DNA probe assay if results were consistently ≥ 1.0 (i.e., $3.0 > \text{ratio} \geq 1.0$) or a single ratio < 1.0(i.e., $0.7 \le \text{ratio} < 1.0$) occurred among other results $\geq 1.0.$

Correlation of the DNA probe assay results with those of culture and clinical data. In this study, true

38897	5	33.20	2.30	6.9

^{*}Two negative controls had values >3 SDs from the mean (negative control No. 1 had a ratio of 0.67; negative control No. 2 had a ratio of 0.63), and they were not used to produce these results.

positive samples were considered to be those specimens that were positive by culture or positive by two non-cultural tests (i.e., DNA probe test and probe competition assay) if culture was negative. The results obtained by DNA probe and culture for asymptomatic and symptomatic patients are shown in Fig 3, a and b, respectively. Fig. 3, c, depicts the data for all patients, regardless of symptoms.

The number of pregnant patients without symptoms included in the study was 257 (Fig. 3, a). Twenty-two patients had positive results by culture alone or two noncultural methods, resulting in a disease prevalence of 8.6%. Four of these patients had discrepant results. One patient was DNA probe positive, but culture negative. This sample was positive for *C. trachomatis* after repeat DNA probe testing (i.e., ratios, 8.35, 9.32). The sample for DNA probe was also submitted in blind fashion for probe competition assay, which verified the

presence of *C. trachomatis* nucleic acid. The three remaining patients were all culture positive and DNA probe negative. The negative results were confirmed by DNA probe competition assay. These probe samples were also retested with the DNA probe assay and all resulted in negative ratios (i.e., patient 42315, ratios = 0.51, 0.45, and 0.28; patient 35543, ratios = 0.17 and 0.25; patient 39971, ratios = 0.48 and 0.37). DNA probe assays performed on the specimens submitted for culture were all positive. The DNA assay demonstrated 98.4% correlation with culture in asymptomatic patients.

The number of symptomatic patients was 169. Seventeen patients had positive results by culture alone or two noncultural methods, with a disease prevalence of 10.1%. Four of these patients had discrepant results (Fig. 3, b). Two patients were positive by culture and negative by DNA probe test. The samples submitted

for the DNA test were subsequently retested with the DNA probe assay. The DNA probe assay was consistently negative for both samples (i.e., patient 37640, ratios = 0.44 and 0.47; patient 28725, ratios = 0.41and 0.38). The probe competition assays verified the absence of C. trachomatis nucleic acid in the specimens submitted. DNA probe assays performed on the specimens submitted for culture were positive. The two remaining patients were negative for C. trachomatis by culture and positive by DNA probe test. The DNA probe test was performed several times on these probe samples and consistently positive results were obtained (i.e., patient 29983, ratios = 1.31, 1.54, and 1.28; patient 26549, ratios = 3.14, 3.56, and 3.58). Probe competition assay confirmed the presence of C. trachomatis nucleic acid in the probe samples. The DNA probe assay demonstrated 97.6% correlation with culture in symptomatic patients.

Fig. 3, c, shows the statistical parameters for the DNA probe test and culture when the results from the patients with and without symptoms were combined. Of the total 426 patients tested, C. trachomatis was detected in 36 (8.4%) specimens by culture and in 34 (8.0%) specimens by the DNA probe test. Overall, the DNA probe test demonstrated 98.1% agreement with culture. For all patients combined, the disease prevalence was 10.1%. There was no statistical difference between DNA probe test and standard cell culture results by χ^2 analysis.

Table II depicts the sensitivity, specificity, positive

and negative predictive values, and 95% confidence intervals for both the DNA probe test and culture in asymptomatic, symptomatic, and combined patient groups using culture or two noncultural methods as the gold standard. Table III depicts the sensitivity, specificity, positive and negative predictive values, and 95% confidence intervals for the DNA probe versus culture alone as the gold standard. Similar results were obtained for both methods of analysis.

Samples that tested negative for C. trachomatis by the DNA probe assay. Table IV shows the distribution of the sample/cutoff ratios for samples that tested negative for C. trachomatis by the DNA probe assay. With the manufacturer's recommended cutoff, 392 of 426 patients in this study were negative for chlamydia. Approximately 96% of these negative samples were at least 50% away from the cutoff value (ratio, ≤0.5). Randomly selected samples from patients with ratios ≤ 0.5 were assayed several times and remained negative (data not shown). Seventeen study patients who were negative for C. trachomatis by the DNA probe test had sample/cutoff ratios >0.5 and <1.0. Sixteen of these patients were negative for C. trachomatis by tissue culture, and only one patient was positive. Repeat testing of this patient by DNA probe assay was performed on the sample submitted for the DNA probe testing. This sample yielded consistently negative results for C. trachomatis (i.e., patient 27348, ratios = 0.53, 0.41, and 0.24). Additionally, probe competition assay performed on this sample confirmed the lack of C. trachomatis nucleic

^{*}A total of 426 study patients were evaluated for the presence of *C. trachomatis* by DNA probe assay and culture. With the manufacturer's recommended cutoff, 392 (92.0%) of the study patients were negative for *C. trachomatis* by the DNA probe assay. †A total of 2703 patients were evaluated for the presence of *C. trachomatis* by DNA probe assay alone. With the manufacturer's recommended cutoff, 2448 (90.6%) of the patients were negative for *C. trachomatis*.

acid in the sample submitted. The DNA probe assay performed on the specimen submitted for culture was positive.

An additional 2703 patient samples were analyzed by DNA probe assay alone during October 1989 and June 1990. The sample/cutoff ratios were determined (Table IV). No matching cultures were performed. Out of 2703 samples analyzed, 2448 (90.6%) specimens were negative for C. trachomatis. Approximatey 5% of patients who tested negative for C. trachomatis had sample/cutoff ratios between 0.5 and 1.0. Eleven patients had ratios >0.9 and <1.0 after initial testing. Nine of these patients were retested by the DNA probe assay. Six patients remained negative for C. trachomatis; however, three of the nine patients were positive for C. trachomatis (i.e., patient 39891, ratios = 0.96, 1.24; and 1.72; patient 33767, ratios = 0.90, 1.08, and 1.00; patient 33342, ratios = 0.98, 1.10, and 1.15). Multiple samples from patients with ratios between 0.8 and 0.9 and between 0.7 and 0.8 were assayed several times. Although all of these samples remained negative after retesting, one sample that had a ratio of 0.77 on primary testing had a single positive ratio when assayed several times (i.e., patient 29435, ratios = 0.77, 1.42, 0.99, 0.67, and 0.55).

Samples that tested positive for C. trachomatis by the DNA probe assay. Table V depicts sample/cutoff ratios in patient samples that tested positive for C. trachomatis by the DNA probe assay. The ratios are shown for all study patients (patients who had a DNA probe assay and a matching culture) and for 2703 patient samples evaluated only by the DNA probe assay without matching cultures. Randomly selected patients with sample/cutoff ratios ≥ 3.0 were retested for C. trachomatis by the DNA probe assay, and all remained positive

(data not shown). Two study patients had sample/cutoff ratios <3.0 and ≥ 1.0 . One patient (i.e., patient 24537, ratio = 2.47) was positive for *C. trachomatis* by culture. The other patient tested negative by culture; however, this patient was clinically symptomatic and was positive for *C. trachomatis* by repeat DNA probe testing on the probe specimen (i.e., patient 25897, ratios = 1.3, 1.5, 1.2). Additionally, probe competition assay confirmed the presence of *C. trachomatis* nucleic acids in this patient's sample.

Of the 2703 patients who had only the DNA probe test performed, 38 (1.4%) had sample/cutoff ratios <1.5 and ≥1.0 . Twenty-six of these patients were retested for *C. trachomatis* by DNA probe assay. Eight patients remained positive for *C. trachomatis*, whereas 17 had negative ratios.

In the same group of 2703 patients, 14 (0.5%) had sample/cutoff ratios <2.0 and \ge 1.5. Eight of these patient samples were retested by the DNA probe assay. Three remained positive for *C. trachomatis*, whereas five had negative ratios after retesting.

Finally, of the 2703 patients who had only the DNA probe test performed, 13 (0.5%) had sample/cutoff ratios <3.0 and ≥ 2.0 . Five of these patient samples were retested by the DNA probe assay, resulting in only one patient with negative ratios for *C. trachomatis* (i.e., patient 29987, ratios = 2.05, 0.46, and 0.98). Randomly selected samples from patients with ratios ≥ 3.0 were assayed several times; all samples remained positive (data not shown).

Comment

Infection by *C. trachomatis* is limited almost exclusively to humans.⁶ It is one of the most prevalent pathogens in the world and is the most common sexually

Table V. Distribution of values in relative light units in patients who tested positive for C. trachomatis by DNA probe assay

		(both DNA assay culture)	Additional patients† (DNA assay only)

^{*}A total of 426 study patients were evaluated for the presence of C. trachomatis by DNA probe assay and culture. With the manufacturer's recommended cutoff, 34 (8.0%) of the study patients were positive for C. trachomatis by the DNA probe assay.

transmitted disease in developed countries. Cell culture has remained the standard for diagnosis, although some studies have estimated that a single endocervical specimen may be only 70% to 90% sensitive for C. trachomatis infection.7.8 Cell culture is technically difficult and requires organism viability and timely transport of specimens to the laboratory for processing. In addition, cell culture is labor intensive, requires trained personnel, and has a routine turnaround time of 48 hours. Demand for simplified and rapid methods of diagnosis has led to development of many antigen detection methods for C. trachomatis infection over the past 10 years. These methods are based on immunodetection of solubilized chlamydia components (enzyme immunoassay) or direct visualization of organisms with chlamydia-specific fluorescein-conjugated monoclonal antibodies (direct fluorescent antibody). Studies comparing these noncultural methods to standard cell culture report sensitivities of enzyme immunoassay of 67% to 98% and sensitivities for direct fluorescent antibody of 72% to 99%.7-10 Barnes6 recently reviewed several studies from 1984 to 1988 comparing enzyme immunoassay with cell culture. These studies demonstrated a range of sensitivity from 70% to 100% and a positive predictive value from 6% to 92%. The prevalence of endocervical infection ranged from 5% to 40%. Similar comparison of direct fluorescent antibody to cell culture in populations with a prevalence of 5% to 27% showed sensitivities from 56% to 100% and positive predictive values from 47% to 100%. Because of the wide range of sensitivities reported in many studies, antigen detection tests have met with mixed acceptance by clinicians for the detection of chlamydial infection. Recently, attention has turned to DNA probes for the detection of infection, and favorable results have been reported with sensitivities of 92%.11

Our study population had a prevalence of infection of 8.6% and 10.1% for asymptomatic and symptomatic patients, respectively. The prevalence of infection in asymptomatic women is comparable to previous reports of 7% to 11%.7, 11, 12 The infection rate in the symptomatic group is lower than expected but comparable to previous reports of 14% to 20%. 9, 11 Our symptomatic group probably does not represent a truly high-risk subpopulation. The DNA probe test performed well in our relatively low-prevalence population.

Comparison of nonculture tests, such as the DNA probe, with culture methods of <100% sensitivity must be interpreted with caution. If culture alone is used as the gold standard, then culture would necessarily have 100% sensitivity. Positive DNA probes might be misinterpreted as being falsely positive rather than culture results being falsely negative. We attempted to address this issue by sending discrepant specimens to another laboratory for DNA probe competition assays. Probe competition assays are reported by Gen-Probe as having 100% correlation with other hybridization techniques. Our results were blinded to the outside laboratory. In this study we defined the number of true positives to be the sum of specimens positive by culture or positive by a DNA probe assay, with confirmation of the presence of C. trachomatis nucleic acid in the sample by probe competition assay. Although this is not standard analysis, other authors have attempted to address this issue similarly with noncultural method confirmation.7-9 We did include standard analytic parameters of test validity with culture alone used as the gold standard (Table III), and, comparable results for the DNA probe were obtained. Overall, the DNA probe performed well with 98% agreement with culture in our study.

In the asymptomatic population, three patients were

[†]A total of 2703 patients were evaluated for the presence of C. trachomatis by DNA probe assay alone. With the manufacturer's recommended cutoff, 255 (9.4%) of the patients were positive for C. trachomalis.

DNA probe negative but culture positive for *C. trachomatis*. DNA probe competition assay was negative in all these samples, indicating that rRNA for *C. trachomatis* was not present in the specimens submitted for the DNA probe assay. DNA probe tests done on the culture-positive specimens were also positive, indicating the presence of probe-detectable DNA sequences. The one patient who was positive for *C. trachomatis* by DNA probe test and negative by culture was found to have *C. trachomatis* nucleic acid present in the probe sample by probe competition assay. The DNA probe assay gave no false-positive results in this patient population.

We obtained similar results with our patient population with symptoms. Two patients were DNA probe negative and culture positive. DNA probe competition assays did not indicate the presence of *C. trachomatis* rRNA. Again, DNA probe tests done on culture-positive specimens were positive indicating the presence of probe-detectable DNA sequences. Two patients were DNA probe positive and culture negative. Probe competition assays verified the presence of *C. trachomatis*; therefore these samples were considered true positives. Overall, the tissue culture method produced three false-negative results, whereas DNA probe assay produced five false negatives.

Tissue culture technique can have a large impact on the ability to isolate *C. trachomatis*. Single passage with shell vials and immunofluorescence staining is standard technique and has been shown to yield high sensitivities. ¹³ Automatic passage of tissue culture specimens has been reported to increase the sensitivity of this method by approximately 3% to 10%. ^{6,14} However, passage with this technique is not commonly practiced in many large clinical institutions. Multiple passages in shell vial systems, in contradistinction to microtiter plates, has not been shown to increase sensitivity of culture. ¹⁴ For these reasons, automatic passage was not done on tissue culture specimens in this study. All discrepant or suspicious specimens underwent a second passage with confirmation of initial results.

Sampling error is the most likely source of discrepant results for both culture and DNA probe assay. Patient specimens for culture and for the DNA probe test were collected with separate swabs. In previous culture versus nonculture evaluations, discrepancy rates of 5% to 13% have been reported as a result of sample variation between multiple swabs. Detection of chlamydia by any method requires the sampling of endocervical cells. Obtaining several swabs and removal of excess mucus has been observed to increase detection rate. Detection rate.

One problem we found with the DNA probe test was the discrete manufacturer recommended cutoff of 300 RLU above the mean of the negative references. The results of 426 culture-matched samples suggested that the manufacturers' recommended discrete cutoff was adequate for determination of results. Our results on 2703 patient samples without matching cultures indicated that samples with sample/cutoff ratios of 0.7 to 3.0 should have repeat testing until unequivocal results are obtained. Out of the 3129 patient samples evaluated by the DNA probe assay in this paper, 124 patients (4.0%) fell into this range. Further study with matching cultures would be helpful to confirm this finding. However, without modification the DNA probe test was equivalent to standard tissue culture in sensitivity, specificity, and positive and negative predictive values for our 426-patient study population, when culture alone or two noncultural methods were used as the gold standard.

The fact sheet from the National Institute of Allergy and Infectious Disease in 1986 recommended that all sexually active women <35 years old be tested yearly for C. trachomatis.17 The DNA probe is a rapid, costeffective method of screening women for infection with 87.2% sensitivity in our low-risk populations. Infection by chlamydia can potentially result in serious long-term sequelae, including ectopic pregnancy, infertility, chronic pelvic pain, and pelvic inflammatory disease. Vertical transmission from mother to fetus has been well established. Recent studies implicate chlamydial infection with increased risk of premature rupture of the membranes, low birth weight, and preterm delivery.3, 4, 18 Rapid tests for diagnosis of chlamydial infection in obstetrics would be of benefit to mother and fetus. Treatment is simple and effective once the diagnosis is made with laboratory confirmation. Positive test results improve diagnostic correlation for the physician and patient treatment compliance and enhance the likelihood that her sex partner will seek referral for evaluation. Coinfecton rate with Neisseria gonorrhoeae can be as high as 50%. The Centers for Disease Control currently recommend presumptive treatment for both organisms if one is detected.19 Specific diagnosis can direct antibiotic therapy for patients and their partners. The DNA probe test also can be used for the detection of both organisms from the same endocervical sample, and results can be made available in approximately 2 hours. In addition, the DNA probe can be a costeffective alternative to cell culture. Our study indicates that the PACE 2 DNA probe is a reasonable alternative to standard cell culture for the rapid diagnosis of chlamydial infection in women. Future DNA probe technology likely will be applied to many other types of infection.

The technical assistance of Leslie Leopold, Mary Rath, Rosemary Gantzer, and the Microbiology Medical Technology Staff is deeply appreciated. We also acknowledge Beth Lucas and Patricia Magevney for coordinating the acquisition of patient samples and their clinical histories. We thank Rick Helmchen and Kimberly Hasselfeld for assistance in data analysis and critical review of the manuscript.

Editors' note

The American Journal of Obstetrics and Gynecology introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case réport, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

Loxoscelism threatening pregnancy: Five cases

Philip C. Anderson, MD

Columbia, Missouri

Envenomation by the spider *Loxosceles reclusa* in five pregnant women proved to have no sustained adverse effects on mother or baby when managed conservatively only with low-dose prednisone. A striking toxic erythema of the skin, common with the bite of the spider, caused the greatest discomfort and concern for the patients but proved to be entirely tractable. No episodes of hemolysis, disorders of coagulation, or renal damage were discovered. There is no clinical evidence of any special risk during pregnancy in the event of loxoscelism. (AM J OBSTET GYNECOL 1991;165:1454-6.)

Key words: Loxoscelism, skin disease

A North American arachnid, the brown recluse spider, properly known as *Loxosceles reclusa*, is the most poisonous house spider in the United States. ^{1, 2} As a result of being carried with household goods and warehouse cargo during the last 50 years, this spider occasionally may be found far beyond its original Midwest habitat. ³ Today, occasional diagnoses of loxoscelism are received from every segment of the nation, often from northern and eastern regions, where envenomations have not been recognized before. No prior reports have been made concerning the course of loxoscelism during pregnancy.

Although no deaths as a result of loxoscelism are fully proved and published, the potential for fatality seems evident. At worst, the bite of this tiny spider may cause an enormous necrotic ulcer of the skin, occasionally as large as 40 cm across and extending into deep muscles; or large amounts of venom may induce sudden severe hemolysis, activate complement, and produce rapid injury to the kidneys or other organs. Children seem particularly susceptible to rapid hemolytic reactions. More pleasantly, the brown recluse spider tries to avoid humans. This nocturnal creature will flee across the skin without biting, unless trapped or assaulted; it seldom occupies busy areas of the home, choosing to hide in closets or in the sides of corrugated cardboard boxes. Importantly, almost all bites are medically insignificant. Unless massive necrosis of the skin results, hematologic complications occur, or unusual apprehension develops (as in the cases reported here), then the physician's care is not essential.

From the Department of Dermatology, University of Missouri-Columbia.

6/1/30080

This report concerns five healthy, pregnant women with medically significant, probable (three of five cases) or proved loxoscelism. The treatment and the wholly favorable outcome for the fetus are described.

The older medical literature failed to establish accurately useful rules for the diagnosis of loxoscelism.⁴ All unexplained necrotic, purple, cutaneous macules of skin are not necessarily spider bites. A physician's visual diagnosis alone—however loud or authoritative the claim—if unsupported by actual material evidence is insufficient for undeniable clinical diagnosis.⁵ Such cases are inappropriate for publication (Table I).

Case reports: Proved loxoscelism during pregnancy

Case 1. A 32-year-old woman, wife of a physician, gravida 2, para 1, 71/2 months pregnant, living in central Illinois, was bitten about noon in late June while sorting clothing and storing cardboard boxes in her basement. She felt "something" run around her waistline and "sting" at her posterior flank. She struck and killed a young Loxosceles reclusa (which was later expertly verified) on the site and saved the "bug" to show her husband. By dinnertime the site was unusually painful, showing a sunken blue macule about 1 cm round, with a small red halo. The patient felt weak and nauseated. By the next morning the pain had worsened, but much more threatening was a bright red maculopapular eruption that spread rapidly all over the skin, especially on the face, associated with the worsening of nausea and with myalgia. Consultation by telephone at 20 hours after the bite furnished these laboratory data: hematocrit, 38%; normal platelet count; white blood cell count, 11,000 cells/mm³ with 80% polymorphonuclear leukocytes; and no free serum hemoglobin. Urine was normal and, most notably, free of blood. Her local physicians opted for bed rest, padding, splinting of the area, and prednisone 40 mg daily, pending further evaluation. No worsening occurred; the trivial laboratory anomalies resolved, and the toxic diffuse erythema of the skin disappeared entirely by the third day. Prednisone was continued to the fifth day. The pregnancy seemed undisturbed, and a wholly normal fetus subsequently was delivered.

Case 2. A 27-year-old woman, gravida I, para 0, 8 months pregnant, who resided in northern Missouri, slipped into her bathrobe and was bitten painfully on the dorsal arm, near the shoulder. She killed a Loxosceles reclusa (proved later) found in her sleeve. While later receiving antihistamines from her personal physician, she became alarmed when the firm, sunken, purple area enlarged almost hourly to reach about 3 to 4 cm in diameter, with a 3 cm halo of erythema around it. When my colleagues and I were consulted almost 80 hours after the bite, the patient's feet were mottled red and swollen, but the bite area had stabilized. The laboratory data were as follows: white blood cell count, 18,000 cells/mm3 with 90% polymorphonuclear leukocytes; platelet count, normal; fibrin split products, <100 µg/100 ml; and urine, positive for free hemoglobin and protein, without any red blood cells seen in the sediment. Bed rest, splinting, elevation of the arm, and padding were started, but corticosteroids were not given because the hemolytic process was judged to be complete at almost 4 days. Recovery was rapid; however, slight proteinuria continued until after delivery. The baby was entirely healthy.

Case reports: Probable loxoscelism

Case 1. A 34-year-old woman, gravida 4, para 3, 6 months pregnant, wife of a physician, was bitten, probably during sleep, in early June. A 2 cm lesion typical of a mild brown recluse spider bite developed on the thigh. Loxosceles spiders were later recovered from the basement ceiling of her home; verified bites are very common in June in the county in which she lives. Seen 48 hours after the bite, she had hemoglobin and protein in the urine and said that she felt "nauseated and ill." The white blood cell count was 10,000 cells/mm³ with a normal platelet count. No drug therapy was started; she recovered fully and was delivered of a normal

Case 2. A 28-year-old physician's daughter, gravida 2, para 1, 6 months pregnant, has a story almost exactly that of the prior case, except that this bite was on the buttock and was a much more necrotic, deeper reaction, 3 to 4 cm across, with more severe pain. The white blood cell count was 34,000 cells/mm³ with 90% polymorphonuclear leukocytes, and the platelet count was depressed <200,000 cu/mm³ for several days. Hemolysis was not detected in serum when the patient was seen 40 hours after the bite, but traces of blood and protein were found in the urine. She took prednisone 60 mg daily for 4 days. The bite was slow to heal but resolved entirely with minimum scarring in 7 months, well after the birth of a normal infant. Her father, a surgeon, had rejected his faith in early, vigorous, wide excision of the bite only because of his daughter's pregnancy (and possibly our advice). Loxosceles spiders are plentiful in her neighborhood.

Case 3. A gravida 1, para 0, 5½ months pregnant farm wife consulted us in July out of concern for a

Table I. Suggested standards for accurate reporting of cases of North American loxoscelism

1. Proved envenomation

- The spider must be recovered immediately and in close proximity to a clinical reaction on skin.
- That spider must be identified by an experienced entomologist and kept for later verification.
- The details of the case must be complete and the patient must be followed up properly with all appropriate expert review of the diagnostic problem.
- 2. Probable envenomation (suitable only for epidemiologic studies)
 - Spiders must be found in the immediate vicinity and these must confirmed by entomologist to be Loxoceles reclusa. Typical proved brown recluse spider bites must be medically well known in the
 - The cutaneous lesion must be wholly typical of loxoscelism, as decided by clinically experienced experts.

3. Possible envenomation

The bite appears typical to experienced physicians; however, no spiders can be recovered in the immediate vicinity. Brown recluse spiders must have been found in the region and other probable or proved bites must have occurred recently.

4. Focal necrosis of the skin

Region has no or few recluse spiders, as verified by entomologists, proved recent loxoscelism is uncommon, and no loxosceles spiders can be recovered in the immediate vicinity of the patient.

generalized severe maculopapular toxic erythematous eruption and increasing general illness in the 3 days after a mild, 1 cm, typical loxosceles bite on the thigh. Laboratory values were reassuring: white blood cell count, 16,000 cells/mm⁸ with 90% polymorphonuclear leukocytes; platelets, normal; and no free serum hemoglobin. Urine had only mild proteinuria (1+) with a trace of blood. She received 40 mg prednisone daily for 3 days, which seemed to her to resolve the rash. She recovered fully and later was delivered of a normal infant.

Comment

In this short series of cases of loxoscelism in pregnancy, no fetus seemed to be harmed, although fearful anticipation was nearly overwhelming for these patients and their families-especially for family members of physicians. In any event no actual medical situation developed that ever seemed to threaten pregnancy.

The generalized toxic erythema of the skin was the single most frightening aspect of the disease. This toxic erythema is a well-known and benign part of loxoscelism and, as a rough rule, may be a favorable sign clinically, suggesting that the patient may possess some prior natural protective immunity. Often this cutaneous reaction is accompanied by some malaise, nausea, headache, and myalgia. Less commonly, persistent hypotensive and vasomotor reactions may be present, lasting at most for a week or two. The toxic rash often appears first as a reticulated erythema or cutaneous flush all over the body then may convert rapidly into a pruritic, or tender, sheet of tiny papules resembling a drug eruption or an exanthem. The rare severe forms of toxic erythema I have seen include facial edema with paresthesia of the scalp and striking edema of hands and feet. Even initially, the hands and feet may appear swollen and deep red or purple, and pain or burning may be felt. Rarely the hands may feel cold and even numb. Tips of fingers, palms, toes, and soles may peel thoroughly 10 to 20 days later, somewhat resembling the streptococcal scarlet fever seen in old photographs.

Diffuse tiny purpura, sometimes alarming in number and persistence, may be a principal feature of the toxic erythema reaction seen with loxoscelism. Because larger purpura or ecchymoses rarely may appear suddenly on hands and feet with the toxic reaction and because both gross clotting anomalies and severe thrombocytopenia can occur in severe systemic loxoscelism, the physician must be satisfied that only the common minor toxic vascular injury, and not a major coagulation disorder, is the cause of the bleeding in the skin. As much as 3 weeks after a bite, peculiar small exacerbations of these toxic purpura may be seen, without other apparent illness. Lacking the assurance of a double-blind study, I suggest that short-term corticosteroid therapy seems to stop or greatly improve this toxic vascular reaction.

The value of a conservative approach to both cutaneous and systemic loxoscelism seems to be well demonstrated in these five cases, as well as in the general literature. In my opinion there is no argument whatsoever to be made for early surgery as therapy for any type of cutaneous loxoscelism. Most brown recluse spider bites are trivial. No one can accurately predict which few bites will progress to systemic disease or to large

cutaneous necrosis. Even those bites that do progress to coagulation disorders are much better managed medically without the complicating issues and effects of surgery. Reparative surgery, about 12 weeks later, may offer some benefits for treating exceptional ulcerations, although most will heal extremely well without surgery. Costs must be considered, too.

I have also reviewed or managed several other cases of possible loxoscelism in pregnancy that could not be included in this report. Cases are few. I know of no instance of a severe coagulation disorder caused in pregnancy by envenomation by any spider or of any case in which the fetus was harmed. Pleasantly, we have never seen sudden renal failure in pregnancy from loxoscelism, as we have seen in cases with brown recluse spider bites of comparable size in children.

Corticosteroid therapy may benefit the toxic erythema and may be helpful in preventing hemolysis and renal injury, but only if given very soon after the bite, before hemolysis is complete. Corticosteroids, even if given very early, do not prevent the development of the ulcer in the skin. Many other drugs have been tried, but none have been convincingly proved to block the cutaneous ulceration.

An entomologist's expert identification of arachnids suspected of causing disease may be obtained by arrangement with my office at no cost, providing only that a clinical report is shared.

Failure to verify high activities of polyamine oxidase in pregnancy serum

Takeshi Kumazawa, MS, Osamu Suzuki, MD, Hiroshi Seno, MD, Shigehiko Mizutani, MD, and Takatoshi Matsumoto, MD

Hamamatsu and Nagoya, Japan

The activity of polyamine oxidase in human pregnancy serum was measured by our new specific method with radioisotopic N¹-acetylspermine as substrate. The activity in pregnancy serum was very low and did not increase during gestation; it was not higher than that in nonpregnancy serum. The high polyamine oxidase activities previously reported by others appear to result from contamination with diamine oxidase, the level of which is high in pregnancy serum. (AM J OBSTET GYNECOL 1991;165:1457-8.)

Key words: Polyamine oxidase, diamine oxidase, pregnancy serum, N¹-acetylspermine

Polyamine oxidase is responsible for conversion of N¹-acetylspermine and N¹-acetylspermidine to spermidine and putrescine, respectively, in mammalian tissues.¹ Free spermine and spermidine also can be substrates for polyamine oxidase, but their activity is much lower than the activity with the acetylpolyamines.² Many data showing high levels of polyamine oxidase activity in human pregnancy serum have been accumulated by a single research group.³-5 In this study we reevaluated polyamine oxidase activity in human pregnancy serum using our new specific method with N¹-acetylspermine tagged with carbon 14 as substrate and failed to confirm high levels of activity.

Material and methods

Chemicals. Pargyline hydrochloride was obtained from Sigma Chemical (St. Louis); semicarbazide hydrochloride was from Kanto Chemical (Tokyo); Amberlite CG-50 (Type I, NH₄+ form) was from Rohm and Hass (Philadelphia); ACS-II scintillator cocktail was from Amersham Co. (Arlington Heights, Ill.). Other chemicals used were of the highest quality commercially available.

Polyamine oxidase assay. Serum samples were collected from 29 healthy pregnant Japanese women at 8 to 40 weeks of gestation. The sera were grouped into early (8 to 12 weeks of gestation), middle (13 to 30 weeks), and late (31 to 40 weeks) stages. Human organs were obtained from four nonpregnant female Japanese cadavers at forensic autopsy; these women were 30 to 60 years old at death. The tissues were homogenized

in 9 volumes of 5 mmol/L potassium phosphate buffer (pH 7.4) and subjected to enzyme assays.

Polyamine oxidase activity was measured by our newly established method.6 The assay mixture (total 0.5 ml) contained 0.1 ml serum or tissue homogenate, 0.05 ml pargyline, a monoamine oxidase inhibitor (final concentration 0.1 mmol/L), 0.05 ml semicarbazide, a diamine oxidase inhibitor (final concentration 1 mmol/L), 0.1 ml 0.5 mol/L potassium phosphate buffer solution (pH 7.4), and 0.18 ml distilled water. The reaction mixture was preincubated at 37° C for 10 minutes, and then the reaction was started by the addition of 0.02 ml N¹-[¹⁴C]acetylspermine (final concentration 0.1 mmol/L). After incubation at 37° C for 60 minutes, the reaction was stopped by adding 0.05 ml of 1 mol/L hydrochloric acid solution. As a blank test, the assay mixture without substrate was incubated; the radioactive substrate was added after the hydrochloric acid solution. The mixture was transferred directly to a minicolumn (0.8 \times 4 cm) of Amberlite CG-50. Then the radioactive reaction product, 3-[14C]acetamidopropanal, was eluted with 5 ml of water. The eluted sample (5 ml) was transferred to scintillation vials containing ACS-II scintillator cocktail, and the radioactivity of the contents of the vials was measured by liquid scintillation counting.

Results

Polyamine oxidase activities were carefully measured and the results are shown in Table I. Polyamine oxidase activity in pregnancy serum was very low and not higher than that in nonpregnancy serum. In addition, the levels of activity did not increase during pregnancy. The activity in retroplacental serum, however, was about twofold higher than that in nonpregnancy serum (p < 0.01). To demonstrate the validity of our assay method, we measured polyamine oxidase activity in tissues of nonpregnant women. The activities in the liver and kidney were about 1000-fold higher than that in the pregnancy serum.

Table I. Polyamine oxidase activities in pregnancy sera and human tissues

	Polyamine oxidase activity (nmol/ml or gm wet weight/60 min)				
Sample	Our study	Results of Morgan's group ^{3-5,8}			
Pregnancy sera					
Early stage	0.20 ± 0.09 $(n = 8)$	1.71			
Middle stage	0.19 ± 0.14 $(n = 5)$	5.09			
Late stage	0.24 ± 0.12 $(n = 16)$	9.20			
Retroplacental sera	$0.63 \pm 0.06*$ $(n = 5)$	292			
Nonpregnancy sera	0.30 ± 0.06 (n = 8)	0.10			
Human liver	239 ± 118 $(n = 4)$				
Human kidney	258 ± 152 $(n = 4)$				
Human brain	65.2 ± 5.0 $(n = 4)$				

Values are means \pm SD. Numbers of samples are in parentheses.

*p < 0.01, by t test, compared with value for nonpregnancy sera.

Comment

Polyamines, such as putrescine, spermidine, spermine, and their acetylated derivatives, are widely accepted to be closely associated with active cell growth, such as in neoplasms and pregnancy. The polyamine levels in plasma were reported to be significantly elevated during late stages of pregnancy.7 Morgan's group^{3-5, 8} reported high levels of activity of polyamine oxidase, an enzyme that is responsible for the metabolism of polyamines and their acetyl derivatives in pregnancy serum (Table I). In our study we used a newly established assay method⁶ for the measurement of polyamine oxidase in human pregnancy serum. It is highly specific, sensitive, and not interfered with by diamine oxidase activity that is very high in pregnancy serum.9-11 As a result, polyamine oxidase activity in pregnancy serum was very low and did not increase during gestation, which is discrepant from the findings of Morgan's group, who used radioactive spermine as substrate (Table I). Their high levels of activity are probably due to contamination by diamine oxidase, which is abundant in pregnancy serum, because spermine is oxidized to some extent by diamine oxidase12, 18 and the resulting radioactive aldehyde product probably is not separated from spermidine, the reaction product of polyamine oxidase for scintillation counting, under their conditions. In their method of polyamine oxidase assay the incubation mixture should have contained 1 mmol/L semicarbazide or aminoguanidine to suppress diamine oxidase activity. However, the sensitivity of their method, after the addition of a carbonyl reagent, will become much lower than that of our method, because polyamine oxidase activity toward spermine is usually much lower than that toward N¹-acetylspermine.²

We have observed significantly higher levels of polyamine oxidase activity in retroplacental serum, although it is almost negligible as compared with that in tissues (Table I). This is probably due to contamination of retroplacental serum by small membrane fragments derived from placental or uterine tissues containing polyamine oxidase during its sampling; such contamination is likely because polyamine oxidase is a ubiquitous membrane-bound enzyme in mammalian tissues.^{2, 14} The polyamine oxidase activity in retroplacental serum reported by Morgan's group is 463-fold higher than that in our study (Table I); their results obviously reflect diamine oxidase activity.

Polyamine oxidase (Enzyme Commission 1.4.3.4) is distinct from diamine oxidase (Enzyme Commission 1.4.3.6), although both enzymes show activities toward spermine and spermidine. Confusion of them is misleading and should be avoided by the use of a specific substrate and/or a specific inhibitor.

Amnioinfusion increases amniotic pressure in pregnant sheep but does not alter fetal acid-base status

Nicholas M. Fisk, MB, Dino A. Giussani, BSc, Michael J. Parkes, DPhil, Peter J. Moore, PhD, and Mark A. Hanson, DPhil

Reading, Berkshire, United Kingdom

To investigate the recent suggestion that fetal hypoxemia and acidemia in polyhydramnios are secondary to raised amniotic pressure, 5 to 15 L of normal saline solution was infused intraamniotically at 100 ml/min in seven ewes. Amniotic pressure increased linearly by 1.0 \pm 0.013 (mean \pm SEM) mm Hg per liter infused. Infusion of 15 L produced a mean rise in amniotic pressure of 15.2 \pm 1.2 mm Hg (p < 0.001) but no significant change in fetal pH, Pco₂, Po₂, fetal heart rate, or mean arterial pressure. A similar rise in amniotic pressure and lack of change in blood gas values occurred in two control ewes infused intraperitoneally. Rupture of the membranes occurred in two of three amnioinfusions of 15 L. We conclude that acute amnioinfusion raises amniotic pressure in sheep but does not alter fetal blood gas status. (AM J OBSTET GYNECOL 1991;165:1459-63.)

Key words: Polyhydramnios, amniotic pressure, fetal blood gases, fetal acid-base status

The excess perinatal morbidity and mortality associated with polyhydramnios are attributable in part to an increased incidence of preterm delivery because of preterm labor and ruptured membranes. Other reasons for adverse perinatal outcome in polyhydramnios include congenital malformations and fetal compromise.

Recent studies in women undergoing invasive procedures have recorded raised amniotic pressures in polyhydramnios, which return toward normal with drainage of amniotic fluid.1-3 It has been suggested that the complications of polyhydramnios may be mediated through raised amniotic pressure.8 In regard to fetal compromise, we have reported significant inverse correlations between amniotic pressure and both fetal pH and Po₂ in 14 pregnancies with polyhydramnios investigated by fetal blood sampling.8 Case reports suggest that fetal condition in polyhydramnios can be ameliorated by reducing high amniotic pressure by drainage of fluid; Tabor and Maier4 noted the disappearance of fetal heart rate (FHR) decelerations as amniotic pressure fell from 50 to 10 mm Hg, whereas we observed that restoration of pressure to within normal limits was accompanied by correction of fetal acidemia and hypoxemia.³ Several authors have thus speculated that raised amniotic pressure in polyhydramnios may impair uteroplacental perfusion.^{1, 3, 4} On the other hand, clinical studies of fetal condition in severe polyhydramnios may be confounded by underlying etiologic conditions such as hydrops and fetofetal transfusion.⁵ Indeed, only a third of the variance in fetal blood gas status in that study³ could be attributed to amniotic pressure.

The aim of this study was to determine, in the sheep, the effect on fetal blood gas status of increasing amniotic pressure by fluid infusion.

Material and methods

Surgical procedure. Chronically instrumented fetal sheep were prepared as previously described6 with standard procedures approved by the host institution and in accordance with United Kingdom legislation. Briefly, anesthesia in nine cross-bred ewes at 116 to 126 days' gestation was induced with thiopental sodium (1 gm given intravenously) and maintained with halothane (1.5% to 2.0% in oxygen). One horn of the gravid uterus was exposed at laparotomy, and the fetal head was delivered through a uterine incision. Catheters were implanted in a fetal carotid artery and the amniotic cavity. An additional polyvinyl catheter of 2 mm inner diameter was implanted for fluid infusion in the amniotic cavity in seven ewes and in the maternal peritoneal cavity in two ewes, that served as controls. The fetus was replaced, the uterus was closed in two layers, and all catheters were exteriorized through the ewe's right flank. At least 5 days was allowed for postoperative

recovery, during which antibiotics were administered to ewe and fetus.

Experiments. Experiments were performed between 121 and 133 days' gestation in the presence of normal fetal pH and blood gas values (mean ± SEM: pH, 7.33 ± 0.01 ; PCO₂, 38 ± 3 mm Hg; PO₂, 22 ± 1.3 mm Hg). Normal saline solution (0.9% sodium chloride) warmed to 38° to 39° C was infused intraamniotically or intraperitoneally at 100 ml/min. Pressures were measured with standard biomedical transducers and recorded on a polygraph run at 0.25 mm/sec. Arterial samples for blood gas analysis were drawn at 10 minute intervals. Amniotic fluid volume at this gestation approximates 1 L7; therefore intraamniotic infusion of 5 L was estimated to increase amniotic fluid volume by >500%. However, in the absence of change in fetal pH and blood gases or maternal disturbance with intraamniotic infusion of this volume, a further 5 L was infused in one ewe and a further 10 L in three ewes. The maternal flank was examined after each liter for evidence of leakage around the catheters and the perineum was inspected for signs of rupture of the membranes. The volume infused intraperitoneally in control fetuses was 15 L. One hour after the infusion, animals were killed with pentobarbital (4 g given intravenously),

and the gross distribution of infused fluid was confirmed at necropsy. There was no evidence of intraperitoneal leakage in the seven ewes that underwent intraamniotic infusion.

Analysis. Mean amniotic pressure was calculated after every liter from point estimates made every 10 seconds over 2 minutes. In the presence of a contraction, the point estimate was obtained after the next return to baseline amniotic pressure. FHR and mean arterial pressure were similarly recorded in five fetuses. Two-way analysis of variance was used over 5 and 15 L to analyze changes in the various parameters $(\Delta = Postinfusion value - Preinfusion value)$, after their distributions were confirmed as normal by histograms. The nonparametric Wilcoxon test was used for testing the significance of overall changes (postinfusion – preinfusion) in animals undergoing infusions of varying volumes. Linear regression analysis was used only after demonstration of lack of residual relationship with the least-squares method.

Results

Amniotic pressure increased with all seven intraamniotic and two maternal intraperitoneal infusions, as shown in Fig. 1. The slopes of the individual regression

4

3

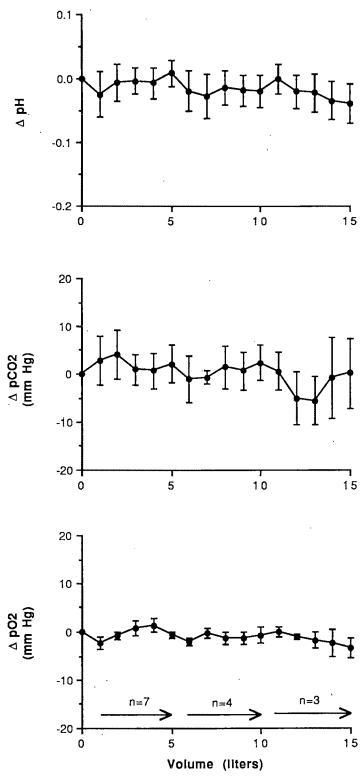

Fig. 2. Mean change in fetal blood gas values with intraamniotic infusion.

equations are shown in Table I. The mean slope in the intraamniotic infusion group (1.00 \pm 0.13) was similar to that in the intraperitoneal infusion group (1.09 ± 0.19) . Although in the intraamniotic infusion group the mean slope was steeper in singleton than in twin pregnancies (1.15 \pm 0.19 and 0.80 \pm 0.13, respectively), this difference was not significant (p = 0.21). In intraamniotic infusions, the slopes were similar in those infused to 5 L compared with those infused to 15 L (1.11 \pm 0.32 and 0.96 \pm 0.11, respectively). There was a significant linear relationship in the intraamniotic infusion group between mean Δ amniotic pressure calculated after each liter, and the volume infused (r=0.96, y=0.96x, p<0.001). Rupture of the membranes was noted at 15 L in two of the three undergoing intraamniotic infusion of this volume, leading to falls in pressure over the next hour of 9.8 and 6.1 mm Hg (58% and 39%, respectively, of the overall Δ amniotic pressure with infusion). The corresponding fall after infusion in the pregnancy with intact membranes infused to 15 L was 3.7 mm Hg (16% of overall Δ).

Intraamniotic infusion over 50 minutes of the first 5 L increased mean amniotic pressure by 4.8 ± 0.7 (SEM) mm Hg (F ratio = 12.6; p < 0.001) but did not produce any significant change in fetal pH $(\Delta = 0.01 \pm 0.02; F = 0.7), Pco_2 (\Delta = 2.2 \pm 3.9 \text{ mm})$ Hg; F = 0.4) or Po_2 ($\Delta = -0.6 \pm 0.6$ mm Hg; F = 1.7). Infusion of a further 5 L in one ewe similarly failed to produce any significant change in fetal blood gases; therefore a total of 15 L was next infused intraamniotically in three ewes, producing a mean rise in amniotic pressure of 15.2 ± 1.2 mm Hg (F ratio = 20.7; p < 0.001) but no significant change in fetal pH ($\Delta = -0.04 \pm 0.03$; F = 0.7) fetal Pco₂ $(\Delta = -0.2 \pm 7.3 \text{ mm Hg; } F = 0.4), \text{ or } Po_2 (\Delta =$ 3.3 ± 2.0 mm Hg, F = 1.7). There was similarly no change in the intraperitoneal infusion group $(\Delta pH = 0.002 \pm 0.002, F = 2.0; \Delta Pco_2 = 0.8 \pm 5.5,$ F = 0.5; $\Delta Po_2 = 0.5 \pm 0.5$, F = 1.2). The median overall change in pH in seven intraamniotic infusions was 0.00 (Wilcoxon p = 0.7); the change was 7.9 mm Hg (p = 0.3) in PcO₂ and -1 mm Hg (p = 0.2) in PO2. Mean values for fetal pH and blood gases after each intraamniotic liter are shown in Fig. 2.

There was no significant change in FHR or mean arterial pressure (F ratio 2.0 and 1.8, respectively) with intraamniotic infusion of 10 L. Furthermore, infusion of another 5 L in two of these fetuses produced no subsequent change in FHR or mean arterial pressure (F ratio 1.5 and 1.1, respectively). Intraperitoneal infusion similarly had no effect on FHR or mean arterial pressure (F ratio 0.4 and 1.0, respectively).

Comment

The lack of effect on fetal blood gas status of raising amniotic pressure over the acute period of this study does not support the recent hypothesis that raised amniotic pressure compromises fetal condition.^{3,4} Human studies suggested that this association of fetal hypoxia with elevated amniotic pressure might be mediated through a reduction in uteroplacental perfusion.^{3,4} Animal studies indicate that uteroplacental perfusion needs to be reduced by ≥50% before any effect of fetal blood gas status is demonstrated.^{8,9} Another mecha-

nism might be umbilical venous compression; again experiments in fetal lambs suggest that acute reductions in umbilical venous flow of <50% produce only a slight reduction in Po₂. Our study only elevated amniotic pressure acutely, and it remains possible that chronic elevations in pressure may affect fetal blood gas status. Nevertheless, the rapid improvement in fetal condition with drainage of amniotic fluid in human polyhydramnios suggests a more immediate effect. A

Although the Δ amniotic pressure after 15 L (15 mm Hg) was at the lower end of the pressure found in human pregnancies complicated by gross polyhydramnios (about 15 to 30 mm Hg),2,3 rupture of the membranes, widely assumed to be a pressure effect, occurred in two of three ewes infused intraamniotically with this volume. Amniotic volume was not measured in this study, in view of the difficulties of ensuring adequate mixing of tracers or dyes in an enlarged and acutely expanding amniotic cavity. In the absence of signs of intraperitoneal leakage, it seems highly likely that some of the infused fluid was absorped into the maternal circulation, either directly or by the fetal circulation.11-13 Consistent with this is our anecdotal observation of maternal polyuria during larger volume infusions. Nevertheless, the aim of this study was to increase pressure rather than volume, and the net effect of any absorption that may have occurred did not prevent the continued rise in pressure with increasing volume or the uterine distension observed at necropsy.

The accuracy of estimates of amniotic fluid volume has been greatly improved by modern measurement techniques involving multiple samplings with different radioactive labeled tracers. The studies of Tomoda et al.7,11 indicate that the normal volume in late-gestation ewes is approximately 1 L. They demonstrated that amniotic fluid volume increases by 110% immediately after a 20-minute intraamniotic infusion of 1 L of normal saline solution but returns to normal 24 hours later.11 Initially we infused 5 L so that the estimated fivefold increase in amniotic volume would be analogous to the human pregnancies complicated by gross polyhydramnios.14 After no effect was achieved on fetal blood gas status and only a modest rise in amniotic pressure was produced, the volume infused was increased to 10 and then 15 L. Intraamniotic infusion of 15 times normal volume not only increased amniotic pressure substantially but also appeared to achieve excesses of amniotic fluid considerably greater than found in human polyhydramnios.

This study confirms previous reports that amnioinfusion increases amniotic pressure. Our group has shown that amnioinfusion of 55 to 500 ml increases amniotic pressure by a mean of 4.7 mm Hg in women with midtrimester oligohydramnios.³ Posner et al.¹⁵ recently showed similar rises with intrapartum amnioin-

fusion at term. In sheep, Gilbert and Brace¹⁸ noted an increase in amniotic pressure of 1 to 2 mm Hg after infusing 1.5 L of water, suggesting an ovine uterine compliance of 1 mm Hg per liter of water. The slope of the linear relationship we observed between amniotic pressure and volume infused not only confirms this suggestion but extends it to infusions of 15 L of normal saline solution. The rise of only 15 mm Hg in amniotic pressure after amnioinfusion of 15 L together with the finding that intraperitoneal compliance is similar to amniotic compliance suggests that the ovine uterus may be relatively more distensible than the human uterus. Indeed, during an epidemic of ovine hydramnios, amniotic volumes of 8 to 18 L were recorded in pregnancies of prolonged gestation.¹⁶

Caution must be exercised before extending these findings to human pregnancies complicated by polyhydramnios, in view of considerable interspecies differences. In contrast to the human uterus, the ovine organ is thin-walled and bicornuate. In addition, sheep have a T-shaped allantoic cavity, one arm of which extends into the nonpregnant horn in singleton gestations, and its presence might conceivably dissipate the effects of increasing amniotic pressure.

The effect of hypothalamic lesions on the length of gestation in fetal sheep

Peter D. Gluckman, MB, DSc,^a Carina Mallard, BSc,^a and Denys P. Boshier, PhD^b Auckland, New Zealand

Twenty-nine sheep fetuses were subject to stereotaxic surgery at 106 to 110 days of gestation. Electrolytic lesions were placed bilaterally in the anterior hypothalamus. Sham-operated controls (n=4) were delivered at 146.3 \pm 4.3 days. Of the fetuses with lesions, two were excluded because histologic confirmation of the lesion was not possible. Those fetuses with bilateral lesions of the suprachiasmatic nuclei (n=4) were delivered at 148 \pm 10 days. In 10 animals with bilateral lesions of the paraventricular nuclei, delivery was significantly (p<0.0001) prolonged to at least 165.6 ± 5.1 days. In nine animals with lesions not involving the endocrine hypothalamus, delivery was at 148.1 ± 4.3 days. All animals that were delivered after 157 days (n=9) had lesions including the paraventricular nuclei bilaterally (p<0.01). The adrenal glands of fetuses with prolonged gestation were normal in weight and light microscopic appearance. These observations demonstrate that fetal neural pathways involving the paraventricular nuclei are essential for parturition in the sheep. However, fetal adrenal growth can continue without such influences. (AM J OBSTET GYNECOL 1991;165:1464-8.)

Key words: Parturition, fetal sheep, hypothalamus, adrenal

The early studies of Liggins et al.1.2 clearly established the role of the adrenocorticotropic axis in determining the length of gestation in sheep. Fetuses subject to hypophysectomy or pituitary stalk section showed prolonged gestation, whereas fetuses treated with glucocorticoids delivered prematurely. Further studies showed that delivery could also be prevented by adrenalectomy. It is now known that the rise in fetal circulating glucocorticoids late in gestation in sheep³ induces the prostaglandin cascade which leads to parturition. However, while such observations clearly show that a fetal pituitary-dependent rise in glucocorticoids is essential for the onset of parturition in sheep,4 the involvement in the fetal brain in this process has been debated.5 It may be that the fetal brain initiates the process by signaling an increase in corticotropin release. Alternatively, the release of pituitary corticotropin may be driven by extraneural influences. A further possibility is that the presence of the fetal pituitary is merely permissive to other influences such as prostaglandins acting directly on the fetal adrenal gland.5

We report the effect of anatomic lesions in two relevant areas of the fetal sheep brain on the length of gestation. Hypothalamic lesions have been induced either in the suprachiasmatic nuclei, which are the major

Reprint requests: Prof. P.D. Gluckman, Department of Paediatrics, University of Auckland, Private Bag, Auckland, New Zealand. 6/1/30436 site of organization of circadian rhythmicity in the postnatal brain,⁶ or in the paraventricular nuclei, which are the presumed sites of cell bodies containing corticotropin-releasing factor.^{7,8} We report that bilateral lesions of the paraventricular nuclei, but not of the suprachiasmatic nuclei, induce a prolongation of gestation.

Methods

Coopworth ewes mated to Dorset rams were used in these studies. The date of mating at Ruakura Animal Research Station was carefully recorded by daily inspection of a ram carrying a crayon harness. Estrus had been synchronized by progesterone sponge withdrawal, and the ewe was removed from the ram once marking was confirmed. The day of marking was termed day 0. Pregnancy was confirmed by ultrasonography at approximately 60 days of gestation. Only singleton pregnancies were used. At 106 to 110 days of gestation, under sterile conditions, the fetal head was exposed at hysterotomy and placed in a stereotaxic frame as previously described.9, 10 Bilateral stereotaxic lesions were inserted either at coordinates anteroposterior 26.0 mm, vertical 6.1 mm, and lateral 0.6 mm relative to stereotaxic zero for lesioning of the suprachiasmatic nuclei or at anteroposterior 24.5 mm, vertical 7.4 mm, and lateral 0.4 mm, which were the coordinates for lesioning of the paraventricular nuclei. A monopolar electrode was used, and the current passed was generally 6 to 10 mA for a period of 30 to 45 seconds. In some fetuses the current was passed for 60 to 90 seconds to induce a larger lesion. The electrode was inserted bilaterally in the coronal plane at an angle of 20 degrees to the vertical to avoid damage to the sagittal sinus. The skull was repaired with cyanoacrylate glue, the scalp replaced, the fetus returned to the uterus, and 80 mg gentamicin was instilled in the uterus, which was closed. No instrument was placed in the uterus, to avoid any effect of exteriorized instrumentation on gestational length.

After surgery the ewes were housed indoors and fed hay and concentrates at will. The lighting cycle was kept constant at 12 hours light and 12 hours dark, and the ewes were inspected daily. If the ewes were in labor, as defined by the presence of blood or membranes in the vagina and obvious contractions, the ewe was anesthetized, the fetus was removed, and its brain perfused. Some fetuses were born alive at vaginal delivery, and these lambs were killed by barbiturate overdosage. If the fetus had not delivered by at least 157 days after conception (which is mean \pm 3 SD gestational length for animals of this flock), the ewe was similarly anesthetized and the fetal brain obtained between 160 and 172 days.

After fixation of the fetal brain, the anatomic site of lesion was confirmed histologically.9, 10 Briefly, the brain was perfused in situ with 100% saline solution, followed by formalin in saline solution as described previously.9, 10 The diencephalic block was embedded in a gelatin-egg albumin mixture, and 50 µm sections were cut and stained by the Nissl method. Particular attention was focused on whether the paraventricular or suprachiasmatic nuclei had been destroyed. The brains were examined without reference to the experimental protocol or knowledge of gestational length. The integrity of the pituitary stalk and the median eminence of the hypothalamus also was inspected.

In addition to the fetuses with lesions, four fetuses were subjected to sham operation in which electrodes were inserted into the general vicinity of the anterior hypothalamus, no current was passed, and the electrodes were withdrawn.

In the latter part of the study, as a result of the observation that some fetuses had prolonged gestations, bilateral adrenal weights were obtained. These had not been recorded for the initial 14 fetuses. These glands were fixed in formalin, sectioned, stained with hematoxylin and eosin, and examined as described previously.11

The lengths of gestation were compared by analysis of variance. Where animals were killed before labor, the age used for gestational length was the age at death.

The protocols were approved by the Animal Ethical Committee of the University of Auckland, and the animals were cared for in accordance with the local institutional guidelines.

Results

Twenty-nine fetuses were operated on, and 4 of them were sham-operated controls, 9 had lesions with coordinates aimed at the suprachiasmatic nuclei, and 16 had lesions aimed at the paraventricular nuclei. Two fetuses were excluded from the analysis; one that aborted at 139 days and one that was delivered stillborn at approximately 147 days; because the neural tissues had undergone autolysis and were not suitable for histologic analysis.

The 27 suitable fetuses were assigned to five groups according to the histologic findings (Fig. 1): those with bilateral lesions of the paraventricular nuclei not involving the suprachiasmatic nuclei or median eminence (n = 4), those with bilateral lesions of the suprachiasmatic nuclei not involving the paraventricular nuclei or median eminence (n = 4), extensive lesions involving bilaterally both the paraventricular nuclei and the suprachiasmatic nuclei (n = 6), those with misplaced lesions of the diencephalon not involving the paraventricular nuclei, suprachiasmatic nuclei, or median eminence (n = 9), and the sham-operated fetuses (n = 4). Of those with misplaced lesions, 5 had rostrally placed lesions in the septal region, and 4 had caudally or dorsally placed lesions lying outside the hypothalamus.

The sham-lesioned fetuses were delivered at 146.3 ± 4.3 (SD) days (range, 142 to 152 days) (Table I). Of the 9 fetuses with misplaced lesions, 1 aborted at 123 days. The remaining 8 were delivered at 148.1 ± 4.3 days (range, 141 to 153 days). Three of 4 fetuses with bilateral lesions of the suprachiasmatic nuclei were delivered at 151 ± 1 days, and 1 was delivered prematurely at 133 days. Of the 4 fetuses with bilateral lesions of the paraventricular nuclei without involvement of the suprachiasmatic nuclei or median eminence, three were killed in utero at 166 to 172 days and the fourth entered labor at 162 days. Of 6 fetuses with more extensive lesions involving both the paraventricular and suprachiasmatic nuclei bilaterally, 2 also had destruction of the median eminence and were killed at 165 and 171 days. The other 4 had an intact median eminence. One was delivered at 156 days and I at 168 days; the other 2 were killed at 170 and 172 days. Thus the mean age at delivery of the 8 animals with lesions of the paraventricular nuclei but with an intact median eminence was $>165 \pm 5.3$ days. There was no overlap between gestational length in animals with lesions of the paraventricular nuclei and the sham or misplaced lesion groups (p < 0.001). By analysis of variance the effect of paraventricular nuclei lesioning on gestational length was significant (p < 0.01); the effect of suprachiasmatic nuclei lesioning was not (p > 0.2). In total, 9 animals failed to deliver within 3 SDs of term gestation (<157 days), and all 9 had lesions of the paraventricular nuclei (Fisher's exact test, p < 0.01).

The adrenal glands were weighed in 4 fetuses with prolonged gestation and in 6 other fetuses. In those fetuses with parturition delayed until >157 days, the

Fig. 2. Photomicrograph of adrenal gland from fetus (k, Fig. 1) with bilateral lesions of paraventricular and suprachiasmatic nuclei; animal was killed at 166 days of gestation. Total adrenal weight was 560 gm; fetal weight was 5.22 kg.

percentage of total gland volume11 for each zone of the gland was: zona glomerulosa, 14% ± 4% for prolonged gestation and $12\% \pm 5\%$ for term gestation; zona fasciculata, $44\% \pm 2.5\%$ for prolonged gestation and $43\% \pm 4\%$ for term gestation; medulla, $32\% \pm 2\%$ for prolonged gestation and 30% \pm 5% for term gestation.

Comment

These observations demonstrate that integrity of the paraventricular nuclei or neighboring areas is essential for the normal initiation of the parturition cascade in sheep. The paraventricular nuclei are the major sites of cell bodies of hypothalamic corticotropin-releasing factor neurons.7.8 It has been previously reported that lesions similar to those in the present study are associated with a reduction in the corticotropin response to hypotension or hypoxia in the fetal sheep. 12 Thus there is compelling evidence that the paraventricular nuclei are involved in the control of corticotropin release in fetal sheep. However, previous observations merely demonstrate that the paraventricular nuclei are essential for stress-related corticotropin release in utero. Our data indirectly suggest that the paraventricular nuclei are necessary for the normal preparturient rise in corticotropin levels3 and that if these paraventricular nuclei are lesioned, corticotropin levels cannot rise sufficiently for the prepartum glucocorticoid surge to occur.

In spite of the presumed absence of a preparturient rise in corticotropin, there was no evidence of adrenal atrophy. In contrast, adrenal atrophy is reported after fetal hypophysectomy.13 It is possible that factors other than corticotropin-releasing factor of paraventricular origin are sufficient for adrenal growth by maintaining

nasal corticotropin secretion. In earlier study of fetuses after paraventricular nuclei lesions were found, basal corticotropin levels were normal although hypoxia- and hypotension-induced corticotropin release was abolished.12 It has been suggested that vasopressin,14 which is secreted by cell bodies in both the paraventricular nuclei and supraoptic nuclei and is found in these nuclei in late-gestation fetal lambs,15 is a stimulus to corticotropin release in utero. However, only the latter could be a source of vasopressin for adrenal maintenance in the fetus with paraventricular nuclei lesions. The possible role of corticotropin-releasing factor of placental origin¹⁶ cannot be discounted. However, whereas these extraparaventricular factors can maintain fetal adrenal growth either directly or indirectly, they alone do not allow the normal parturition cascade to occur.

The signal for the prepartum rise in paraventricular nuclei-induced corticotropin release in late gestation in the fetal sheep is not known. Among the hypotheses that have been proposed is that the rise is determined by an intrinsic fetal circadian oscillator. A number of fetal circadian rhythms have been described; these include rhythms of fetal breathing and electroencephalographic activity,17 fetal prolactin,18 and cortisol release.19 The latter may well be secondary to changes in maternal cortisol production; however, the basis of the fetal diurnal rhythms in prolactin and electrophysiologic activity is not known. It has been reported that there is a diurnal rhythm in cerebrospinal fluid arginine vasopressin concentrations.20 As arginine vasopressin in the cerebrospinal fluid originates in the suprachiasmatic nucleus21-23 and not in the magnocellular system,

this rhythm is indirect evidence that suprachiasmatic nuclei do exhibit circadian rhythmicity in fetal sheep. Circadian rhythmicity of metabolic activity has been shown in fetal suprachiasmatic nuclei both in the rhesus monkey24 and in the rat.25 Thus it is not unreasonable to suggest that the fetal suprachiasmatic nuclei show circadian oscillation in fetal sheep. However, our studies clearly show that the suprachiasmatic nuclei do not play a major role in determining the length of gestation in this species. In our studies there were four fetuses with complete destruction of the suprachiasmatic nuclei, and all were delivered before 152 days of gestation. The slight tendency to longer gestation in some of these may be due to the lesions impinging on pathways linking the anterior hypothalamus to the paraventricular nuclei and thus partially affecting corticotropin release.

While the suprachiasmatic nuclei may have no role to play in the timing of the length of gestation, our observations do not preclude the possibility that they play a role in the temporal timing of delivery. It has previously been suggested in the rat that, in addition to a biologic clock that determines the length of gestation, there may be an independent clock that determines when, within a window of gestational length, delivery actually occurs.26 Such a gating system has been used to explain the circadian rhythm in the time of delivery, which is particulary marked in some species. We do not have sufficient data to address this question in this study.

We thank Dr. J. Smith, Ruakura Animal Research Station, for supervising the mating.

Lymphocytes stimulate progesterone production by cultured human granulosa luteal cells

Nobuyuki Emi, MD, Hideharu Kanzaki, MD, Masumi Yoshida, MD, Kenji Takakura, MD, Masatoshi Kariya, MD, Norihiko Okamoto, MD, Kimitoshi Imai, MD, and Takahide Mori, MD

Kyoto, Japan

After follicular rupture, massive invasion of blood vessels with neovascularization of the developing corpus luteum takes place, providing many chances for direct contact of luteal cells with resident and migrating immune cells. We studied the effects of peripheral blood lymphocytes on progesterone production by human granulosa luteal cells isolated from women undergoing in vitro fertilization. During 6 days of culture. progesterone production by granulosa luteal cells was significantly increased when they were cultured together with autologous or allogenic peripheral blood lymphocytes. This stimulatory effect was also observed on the addition of medium conditioned with peripheral blood lymphocytes and was synergistic with gonadotropin stimulation. The activity was present in the fraction retained by ultrafiltration with a 30,000 molecular weight cutoff filter and was preserved after heating at 56° C for 30 minutes but disappeared after heating at 70° C for 15 minutes. These findings suggest that lymphocytes infiltrating the corpus luteum during early luteinization can stimulate the function of human granulosa luteal cells through the action of some protein-like humoral factor(s) of higher molecular weight than that of previously identified lymphokines and indicate a possible paracrinologic regulatory role for lymphocytes in ovarian function. (AM J OBSTET GYNECOL 1991;165:1469-74.)

Key words: Human granulosa luteal cell, progesterone production, lymphocyte, cytokine

In recent years a growing body of evidence has accumulated to suggest that the immune system is an additional local regulator of ovarian function. It is well known that immunoincompetent or immunosuppressed animals show numerous reproductive disorders.1-8 Thymic control of ovarian function has clearly been demonstrated by the experimental induction of oophoritis in neonatally thymectomized mice.4.5 Macrophages have been identified in the developing corpus luteum in several species, including man,6-8 and have been suggested to be putative intraovarian regulators. One macrophage-derived cytokine, interleukin-1, has been observed to suppress the functional and morphologic luteinization of cultured murine and porcine granulosa cells.9, 10 Another cytokine, tumor necrosis factor-α, has been reported to inhibit the gonadotropin-dependent differentiation of murine granulosa cells and to cause complex dose-dependent alterations in the elaboration of progesterone and androstenedione. 11-13 On the other hand, lymphocyte secretory products (lymphokines) have been shown to have an effect on steroidogenesis in cultured rat granulosa luteal cells. However, it is unclear whether the function of granulosa luteal cells can be modulated by other immune cells, especially lymphocytes, which should play a central role in the immune response, and whether the stimulatory effect can be observed in an autologous combination occurring inside ruptured follicles in vivo. Accordingly, we examined the effect of lymphocytes of autologous origin and the conditioned medium derived from lymphocytes on progesterone production during the culture of granulosa luteal cells obtained from patients at oocyte retrieval in our in vitro fertilization program. The ovarian stimulation was controlled completely by exogenous gonadotropins that mimic the normal ovulatory cycle. Thus granulosa luteal cell culture for 6 days after oocyte retrieval is considered to be an appropriate in vitro model for studying early luteinization.

Material and methods

Granulosa luteal cells were obtained from patients undergoing superovulation in the in vitro fertilization program at Kyoto University Hospital. They had primary or secondary infertility with fallopian tube occlusion but no endocrinologic disorders. Follicular development was induced with 150 IU human menopausal gonadotropin (Pergonal, Teikoku-zoki, Tokyo) given

from day 3 of the cycle and with 900 µg gonadotropinreleasing hormone analog (buserelin acetate, Hoechst Japan, Tokyo), provided as a nasal spray, daily from day 1 of the cycle. Follicular maturation was assessed each day by measurement of serum estradiol levels and ultrasonographic scanning. When the leading follicle reached 18 mm in diameter, human menopausal gonadotropin was discontinued and 5000 IU human chorionic gonadotropin (hCG) (hCG Mochida, Mochida Pharmaceutical, Tokyo) was injected 52 hours after the last human menopausal gonadotropin administration. Oocytes were recovered 36 hours after the injection of hCG through the ultrasonographically guided transvaginal route.

Granulosa luteal cells were obtained by using a heparinized buffer (Dulbecco's phosphate-buffered saline solution, Gibco, Grand Island, N.Y.) to wash the follicles so as to enhance the recovery of oocytes. After removal of the oocytes, the granulosa luteal cells were pooled, centrifuged at 200 g for 20 minutes, and resuspended in RPMI 1640 medium (Gibco). Separation of the granulosa luteal cells from red blood cells was achieved with a Ficoll gradient (Lymphocyte Separation Solution, Nakalai Tesque, Kyoto). The viability of the granulosa luteal cells was assessed by trypan blue staining and was usually >90%. The granulosa luteal cells were then centrifuged and resuspended in RPMI 1640 medium containing 10% fetal calf serum and 100 U/ml penicillin (complete medium). The cells were plated at a density of 1 × 10⁵ viable cells per well in 24-multiwell culture plates (Corning Glass Works, Corning, N.Y.) containing 1 ml complete medium and precultured for 24 hours at 37° C under humidified 5% carbon dioxide in air.

Peripheral blood mononuclear cells were isolated from male or female volunteers by means of centrifugation with a Ficoll gradient at 24 hours after oocyte retrieval. Peripheral blood mononuclear cells were resuspended in complete medium and then counted with a hemacytometer. They were then incubated for 1 hour at 37° C in plastic dishes that had been precoated with autologous serum for 15 minutes at 37° C. Nonadherent cells were collected from the dishes and were shown to contain <5% monocytes by immunofluorescence staining by Leu M3 monoclonal antibody (Becton-Dickinson Immunocytometry System, Calif.). These cells were defined as peripheral blood lymphocytes. The adherent cells were removed from the dish by incubation for 15 minutes with ethylenediaminetetraacetate (1:5,000, Gibco) at room temperature followed by gentle scraping with a rubber policeman. They contained >96% Leu M3-positive cells and were defined as monocytes.

Granulosa luteal cells were cultured for 6 days with the medium being replaced every 2 days, and the basal progesterone production was determined. To examine the effect of hCG on progesterone production, hCG was added to the granulosa luteal cell culture in concentrations from 5 to 50,000 mIU/ml. Autologous or allogenic peripheral blood mononuclear cells, peripheral blood lymphocytes, and monocytes prepared as described were added to the precultured granulosa luteal cells at a density of 1×10^4 to 2×10^6 viable cells per well. Each well contained 2 ml complete medium, and cells were added in the presence or absence of hCG (500 mIIU/ml). All cultures were prepared in triplicate, and the number of granulosa luteal cells in each well was counted by the citric acid—crystal violet method at the completion of culture.

Conditioned medium was prepared by culturing autologous or allogenic peripheral blood lymphocytes in complete medium for 6 days and added to granulosa luteal cell cultures. In addition, we examined the effect of conditioned medium after heat treatment (56° C for 30 minutes and 70° C for 15 minutes). Conditioned medium from peripheral blood lymphocytes was also prepared in RPMI 1640 containing 0.5% bovine serum albumin (BSA, Sigma, St. Louis) and subjected to ultrafiltration with a centrifugal microconcentrator (Centricon-30; 30,000 molecular weight cutoff; 2000 g for 30 minutes; Amicon Division, W.R. Grace, Danvers, Mass.). The retained or filtered fractions were added to the granulosa luteal cell cultures.

Spent culture medium was frozen and assayed for progesterone by radioimmunoassay with a commercial kit (progesterone—iodine 125 kit; Sorin Biomedica, Saluggia, Italy). Progesterone production was expressed in micrograms per 10^5 cells per 48 hours or 6 days. All data are presented as the mean \pm SD of triplicate cultures. Student's t test was used for statistical analysis.

Results

Cultured granulosa luteal cells derived from preovulatory follicles after exogenous administration of hCG in vivo secreted large amounts of progesterone during the first 2 days of culture. In the subsequent culture period, from 2 to 6 days, basal progesterone production tended to decrease. Progesterone production by granulosa luteal cells was little enhanced even by the addition of hCG during the first 2 days of culture. However, from 2 to 6 days, the level of progesterone production of granulosa luteal cells could be boosted by doses of 50 to 50,000 mIU/ml hCG (Fig. 1).

When 1×10^5 granulosa luteal cells were cultured with various densities of autologous peripheral blood mononuclear cells, 1×10^4 or 1×10^5 peripheral blood mononuclear cells did not affect progesterone production by granulosa luteal cells in comparison with

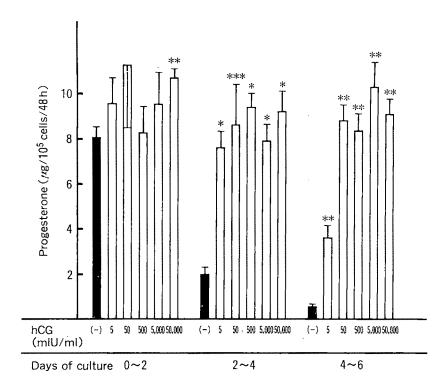

Fig. 1. Basal and hCG-treated progesterone production and effect of hCG on progesterone production by granulosa luteal cells. Five to 50,000 mIU/ml hCG was added to the granulosa luteal cell culture. Asterisk, p < 0.001; two asterisks, p < 0.01; three asterisks, p < 0.05 (all vs control).

the controls. However, 1×10^6 and 2×10^6 autologous peripheral blood mononuclear cells caused a significant increase in progesterone production (p < 0.05, Fig. 2). A similar stimulatory effect of peripheral blood mononuclear cells on progesterone production by granulosa luteal cells was observed when granulosa luteal cells were cultured with 1 × 106 peripheral blood lymphocytes separated from peripheral blood mononuclear cells, but was not observed during culture with 1×10^6 monocytes (Fig. 3). One million fresh human erythrocytes cultured with granulosa luteal cells failed to stimulate progesterone production, indicating that the stimulation of granulosa luteal cells was not due to simple cell-cell contact (Fig. 3). Progesterone and hCG were not detectable in the culture medium when peripheral blood lymphocytes were cultured alone (data not shown).

Granulosa luteal cells were cultured with 1×10^6 autologous peripheral blood mononuclear cells in the presence or absence of hCG (500 mIU/ml). An additive effect of peripheral blood mononuclear cells and progesterone production was also observed in granulosa luteal cells cultured with hCG (Fig. 4). Progesterone was not detectable in the medium of peripheral blood mononuclear cells cultured with hCG (data not shown).

Conditioned medium derived from peripheral blood lymphocytes and added to granulosa luteal cell culture had a significant stimulatory effect on progesterone

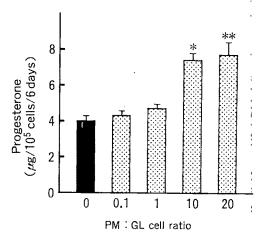

Fig. 2. Effect of autologous peripheral blood mononuclear cells (*PM*) on progesterone production when cultured with granulosa luteal (*GL*) cells. Peripheral blood mononuclear cells (1×10^4 to 2×10^6 cells) were added to 1×10^5 granulosa luteal cells, so ratio of peripheral blood mononuclear cells to granulosa luteal cells ranged from 0.1 to 20. *Asterisk*, p < 0.01; two asterisks, p < 0.05 (all vs control).

production in a dose-dependent manner. There was no difference in the stimulatory effect between the conditioned medium derived from autologous and allogenic peripheral blood lymphocytes (Fig. 5). Counting of granulosa luteal cells at the completion of culture showed no increase in numbers.

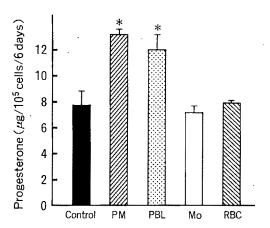

Fig. 3. Effect of autologous peripheral blood mononuclear cells (*PM*), peripheral blood lymphocytes (*PBL*), monocytes (*Mo*), and erythrocytes (*RBC*) on progesterone production by granulosa luteal cells. One million peripheral blood mononuclear cells, peripheral blood lymphocytes, monocytes, or erythrocytes were added to 1×10^5 granulosa luteal cells and cultured for 6 days. *Asterisk*, p < 0.05 (vs control).

^{*}p < 0.05 (vs control).

The retained fraction of conditioned medium derived from peripheral blood lymphocytes after Centricon-30 ultrafiltration significantly stimulated progesterone production by granulosa luteal cells in a dose-

dependent manner, but the filtrate failed to stimulate progesterone production, suggesting that the molecular weight of the stimulatory factor(s) secreted by peripheral blood lymphocytes was more than 30,000 (Table I). Heating of conditioned medium at 56° C for 30 minutes did not alter its stimulatory activity, but the activity was abolished by heating at 70° C for 15 minutes (Table II).

Comment

In this study we demonstrated that secretory products from lymphocytes can stimulate granulosa luteal cell steroidogenesis in vitro in humans. When granulosa luteal cells were cultured together with peripheral blood lymphocytes, progesterone production was increased, and there was no difference in the stimulatory effect of autologous and allogenic peripheral blood lymphocytes. Moreover, the conditioned medium derived from cultured autologous or allogenic peripheral blood lymphocytes also stimulated progesteroné production by granulosa luteal cells in a dose-dependent manner.

Soon after ovulation numerous blood cells rapidly infiltrate the ovarian granulosa cell layer, which is localized in an avascular area defined by the basement membrane before ovulation, and thus come into direct contact with the granulosa cells. Recently, unidentified macrophage factor(s) were found to stimulate progesterone production by murine14 and human15 granulosa luteal cells in vitro. However, the macrophage-derived cytokines interleukin-19, 10 and tumor necrosis factorα¹¹⁻¹³ have been shown to suppress luteinization, implying that there exists a complex regulatory mechanism for ovarian function involving macrophages. In mice, cell-cell contact has been proved to be an essential component of this stimulatory effect of macrophages. 16 On the other hand, the secretory products from concanavalin A-stimulated lymphocytes have been found to stimulate progesterone production by cultured rat granulosa cells.17 In this study we examined the effect of peripheral blood lymphocytes on the luteal function through culture with autologous peripheral blood lymphocytes and granulosa luteal cells as an in vitro model of the early stage of luteinization. Granulosa luteal cells collected from aspirates of mature preovulatory follicles had acquired the capacity for progesterone production by hCG administration. Before starting the experiments, granulosa luteal cells separated on a Ficoll gradient were precultured for 24 hours to allow adhesion to plastic to remove contaminating blood cells. It seems that the level of progesterone production by granulosa luteal cells during the first 48 hours of culture was not increased by the addition of hCG, probably because they had a refractoriness to hCG early in the culture by the high amount of exogenously adminis-

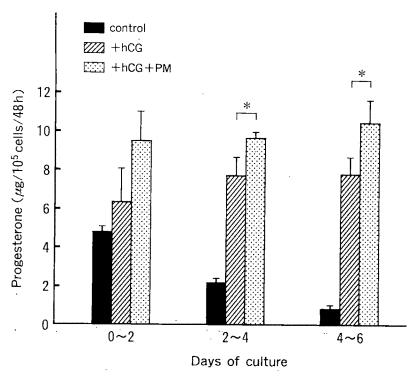

Fig. 4. Effect of peripheral blood mononuclear cells (PM) on progesterone production by hCGtreated granulosa luteal cells. One hundred thousand granulosa luteal cells were cultured with 1×10^6 autologous peripheral blood mononuclear cells in presence or absence of hCG (500 mIU/ml). Asterisk, p < 0.05 (vs culture with hCG only).

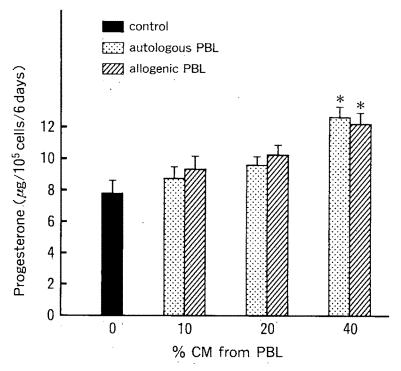

Fig. 5. Effects of conditioned medium (CM) obtained from autologous or allogenic peripheral blood lymphocytes (PBL) on progesterone production by granulosa luteal cells. Conditioned medium obtained from autologous or allogenic peripheral blood lymphocytes was prepared as described in Material and methods and was added to granulosa luteal cell culture. Asterisk, p < 0.05 (vs control).

tered hCG 36 hours before oocyte retrieval.¹⁸ In contrast to the previous report of Halme et al.¹⁵ we could not find a significant stimulatory effect of monocytes or macrophages on granulosa luteal cell progesterone production. In fact, stimulation was observed in cultures of granulosa luteal cells and peripheral blood lymphocytes from which adherent cells (monocytes or macrophages) had been removed.

To determine whether cell-cell contact between granulosa luteal cells and peripheral blood lymphocytes was essential for stimulation of progesterone production, we examined the effect of conditioned medium obtained from peripheral blood lymphocytes on progesterone production by granulosa luteal cells. Conditioned medium derived from peripheral blood lymphocytes cultured for 6 days was found to stimulate progesterone production significantly in a dose-dependent manner, suggesting that the direct contact of peripheral blood lymphocytes and granulosa luteal cells was not required in humans, in contrast with mice.16 This stimulatory effect of the conditioned medium from peripheral blood lymphocytes, which contained no or very few monocytes or macrophages, supported the findings observed in the culture system mentioned above.

The humoral stimulator(s) survived heating at 56° C for 30 minutes and lost its activity after 15 minutes at 70° C; the stimulatory activity was found in the retained fraction after processing with a Centricon-30 and not in the filtrate. These findings suggest that the humoral factor(s) that stimulates progesterone production by granulosa luteal cells seems to be a protein-like substance with a molecular weight of >30,000. The factor(s) cannot be interferon-y, interleukin-1, interleukin-2, and transforming growth factor-β, since all of these cytokines did not stimulate progesterone production by granulosa luteal cells in our granulosa luteal cell culture system (unpublished observations). In the light of these results, the humoral factor(s) responsible for granulosa luteal cell stimulation might be an unidentified cytokine(s) released from lymphocytes.

Peripheral blood lymphocytes had an additive effect on progesterone production by hCG-treated granulosa luteal cells. The stimulatory effect of hCG on progesterone production by granulosa luteal cells reached a plateau when >50 mIU/ml hCG was added. However, an additive effect of culture with peripheral blood lymphyocytes was found when as much as 50 mIU/ml hCG was added to the granulosa luteal cells, suggesting the existence of mechanisms other than hCG for stimulating granulosa luteal cell function.

In this study we demonstrated that autologous peripheral blood lymphocytes can stimulate progesterone production by granulosa luteal cells and that the stimulation is mediated by unidentified product(s) secreted from lymphocytes. Further investigation is needed to

characterize the luteotropic factor(s) secreted by lymphocytes.

We thank Miss Masako Shimizu for her excellent technical assistance with the radioimmunoassay and Dr. Masatsune Fukuoaka for advice on this manuscript.

Postbinding insulin resistance around parturition in the isolated rat epitrochlearis muscle

Nagayasu Toyoda, MD, Tsukio Deguchi, MD, Kazuhira Murata, MD, Toshihiko Yamamoto, MD, and Yoichi Sugiyama, MD

Tsu, Mie, Japan

To determine whether insulin resistance exists in maternal skeletal muscle during pregnancy and how it returns to normal during the postpartum period, 3-O-methyl[¹⁴C]-p-glucose transport and [¹²⁵l]insulin-binding activities were measured in isolated rat epitrochlearis muscle. Maximally insulin-stimulated methylglucose transport activity was decreased on day 20 of pregnancy and on days 1 and 4 post partum; it returned to the nonpregnant level by day 9. The insulin-binding activity did not change significantly throughout pregnancy, increased on days 1 and 4 post partum, and returned to the nonpregnant level by day 9. There was no significant difference in insulin binding or insulin-stimulated methylglucose transport activity between lactating and nonlactating animals. These results suggest that insulin resistance caused by postbinding changes in epitrochlearis muscle develops during late pregnancy and continues at least until day 4 post partum. Lactation does not appear to have a significant effect on insulin resistance. (AM J OBSTET GYNECOL 1991;165:1475-80.)

Key words: Insulin resistance, insulin receptor, glucose transport, pregnancy, lactation

Insulin resistance during pregnancy is a key phenomenon for understanding the mechanism of maternal metabolic adaptation for supplying glucose to the fetus and also for understanding the pathophysiologic characteristics of gestational diabetes mellitus, which may develop if an increase in insulin secretion cannot meet an increase in insulin resistance.

Peripheral insulin resistance during pregnancy has been demonstrated in vivo by a number of experiments, including glucose clamp studies in humans,¹ rats,² and rabbits³ and hind-limb perfusion studies in rats.⁴ However, the results of in vitro studies with isolated tissues have been somewhat conflicting. Some have observed insulin resistance in isolated adipocytes from humans⁵,6 and rats,^{7,8} but others have not observed resistance in isolated adipose tissues° or adipocytes.¹⁰ Although skeletal muscle is the major tissue responsible for peripheral glucose use,² there have been few reports on this subject with the use of isolated skeletal muscle. One article¹¹ could not find any insulin resistance in isolated soleus muscle from pregnant rats.

Our previous experiment⁸ with isolated adipocytes from pregnant rats near term revealed insulin resistance in terms of methylglucose transport activity, and one of the aims of this study is to determine whether a discrepancy exists between the results with isolated adipocytes and those with isolated skeletal muscle. The second purpose of this study is to demonstrate how maternal tissue recovers from its insulin-resistant state after parturition. The last purpose is to determine whether lactation has any effect on insulin resistance.

To answer these questions, we examined changes in methylglucose transport and insulin-binding activities in isolated epitrochlearis muscle strips from rats during pregnancy and the postpartum period, with or without lactation.

Material and methods

Animals. Sprague-Dawley rats 6 weeks old were purchased from Shizuoka Laboratory Animal Center (Hamamatsu, Japan) and were taken care of in the Institute of Laboratory Animals of Mie University School of Medicine, which approved our experiments. The rats were fed at will in an air-conditioned room at 23° C with 60% humidity, light from 7 AM to 7 PM, and dark from 7 PM to 7 AM. The day on which sperm was found in the vagina was designated as day 0 of pregnancy. The rats were killed at 10 to 11 weeks of age for the experiments on days 10, 15, and 20 of pregnancy and days 1, 4, and 9 post partum, as were virgin rats for the controls. The groups at 4 and 9 days post partum were divided into two groups, lactating and nonlactating. The pups of the nonlactating group were removed from the mother on day 1 post partum.

Isolation of epitrochlearis muscle. The rats were

6/1/30443

decapitated between 11 AM and 3 PM, and a pair of epitrochlearis muscle pieces was removed within 5 minutes. Immediately after the pieces were weighed, they were put into ice-cold medium until the experiment was started. The medium (pH 7.4) was composed of Krebs-Henseleit bicarbonate buffer bubbled with mixed gases (95% oxygen and 5% carbon dioxide), 0.1% bovine serum albumin (fraction V, A-4503, Sigma, St. Louis), and 2 mmol/L sodium pyruvate (Sigma).

3-O-Methylglucose transport activity. Methylglucose transport activity was assessed by a modification of the method described by Wallberg-Henriksson et al. 12 A piece of epitrochlearis muscle was incubated in a polypropylene tube for liquid scintillation (volume, 20 ml) containing 2.0 ml of medium without insulin, and another piece was incubated with 100 nmol/L insulin with shaking back and forth at 110 cycles/min for 30 minutes in an incubator at 37° C. Then each piece was transferred into medium with the same amount of insulin but containing 3-O-methyl[14C]-D-glucose (0.1 μCi; ICN Radiochemicals, Irvine, Calif.) and L-[3H]glucose (0.05 μCi; New England Nuclear, Boston) and incubated under the same conditions. After a 10minute radioactive incubation with insulin or after a 30-minute radioactive incubation without insulin, the piece was recovered and blotted on a sheet of filter paper to remove the medium and frozen in liquid nitrogen. The piece was homogenized by a glass homogenizer with 15% trichloracetic acid, then centrifuged at 1600 g for 10 minutes at 4° C. The radioactivity (disintegrations per minute of carbon 14 and tritium) of 0.8 ml of the supernatant was measured in scintillant (Univer-Gel II, Nakarai Chemicals, Kyoto) by a liquid scintillation counter (Rackbeta 1219, Wallac, Turku).

The amount of methylglucose transported into the cells was calculated by subtracting the nonspecific association of the radioactivity, which was assessed by the radioactivity of L-[³H]glucose. Transport activity was expressed by clearance of methylglucose from the medium per wet weight of the muscle strip (nanoliters per minute per milligram).

Adenosine triphosphate measurements. Adenosine triphosphate levels in the muscle strips just after removal from a rat and after the transport experiment were assessed as follows. A muscle piece was homogenized in 1 ml of cold saline solution and centrifuged at 1600 g for 10 minutes at 4° C. The adenosine triphosphate content of the supernatant was measured by an assay kit (Sigma) that used a bioluminescent method.

Insulin-binding activity. A pair of muscle pieces was incubated at 15° C with shaking at 110 cycles/min in medium containing [A14- 125 I]insulin (0.05 μ Ci; Amersham, Buckinghamshire, U.K.) with or without 10 μ mol/L insulin. The temperature of 15° C may be con-

sidered as unphysiologic. However, at higher temperature increased degradation and internalization of insulin may not reflect true insulin receptor—binding activity.

After 4 hours' incubation, the pieces were transferred to a sheet of filter paper to remove the medium. The radioactivity associated with the muscle pieces was counted in a well-type scintillation counter (ARC 600, Aloka, Tokyo). The specific binding activity was estimated by subtracting the nonspecific binding, which was the amount of [1251]insulin associated with the muscle piece in the presence of 10 µmol/L of insulin. The specific binding activity was expressed as a percent of the total insulin added to the incubation medium per 100 mg wet weight of the muscle.

The degradation of [125 I]insulin during the incubation was estimated by means of trichloracetic precipitation. 13 A portion of the medium after a 4-hour incubation was put into 1 ml of Krebs-Henseleit buffer containing bovine serum albumin, and 1 ml of 15% trichloracetic acid was added. After centrifugation at 1600 g for 10 minutes, the radioactivity of the supernatant and the precipitate was counted.

Serum insulin and blood glucose assays. The serum was separated from the blood within 15 minutes after it was obtained from the animals by decapitation and frozen at -80° C until the hormone assays. Serum insulin was assayed by a radioimmunoassay kit (Dinabot Japan, Tokyo). The blood glucose levels were measured by a glucose analyzer (model 23A, Yellow Spring Instruments, Yellow Springs, Ohio).

Statistics. We used unpaired, one-tailed t tests to determine differences between values in the control and in the pregnant or postpartum rats. The significant changes in insulin binding and glucose transport activities throughout pregnancy and the postpartum period also were confirmed by analysis of variance. Statistical significance was determined at the p < 0.05 level.

Results

Assessment of the experimental procedure. Each of the following assessments was done by five separate experiments. It was determined that the methylglucose transport activity increased linearly up to 15 minutes with 100 nmol/L insulin and up to 45 minutes without insulin. The maximal transport activity was obtained at insulin concentrations of ≥1 nmol/L. The subsequent transport experiments were performed for 10 minutes for assessing maximally insulin-stimulated glucose transport activity and 30 minutes for basal glucose transport activity.

Adenosine triphosphate levels (nanomoles per milligram wet weight) in the muscle pieces just after removal from the rats and after the incubation for methylglucose transport with or without insulin were

Values are mean ± SE.

 2.17 ± 0.09 , 2.13 ± 0.19 , and 2.08 ± 0.09 (mean \pm SE, n=5), respectively, and no significant difference was found.

A time course of the insulin binding activity shows a plateau after 4 hours, and a 4 hour-incubation time was adopted for the following experiments. From the displacement curve of specific [125I]insulin-binding activity by unlabeled insulin, the insulin concentration that gives half-maximal [125I]insulin binding is estimated at about 10 nmol/L (figures not shown).

The percentage of [125] insulin degraded during binding incubation was not significantly different between the experimental groups (15.4% as the mean of all samples).

Fundamental characteristics (Table I). The mean body weight was significantly increased during pregnancy and on day 9 post partum but significantly decreased on day 1 post partum. Food intake was significantly increased during pregnancy and on day 4 post partum with lactation and on day 9 post partum with or without lactation, although it was significantly decreased on day 1 post partum. The wet weight of the muscle pieces was not significantly different among the groups. The blood glucose levels were significantly decreased on days 15 and 20 of pregnancy and on day 1 post partum but increased on day 4 post partum without lactation. The serum insulin levels were significantly decreased on day 20 of pregnancy and on day 4 post partum with lactation.

Methylglucose transport activity (Fig. 1). Maximally insulin-stimulated methylglucose transport activity in the muscle pieces from rats on day 20 of pregnancy and on days 1 and 4 post partum with or without lactation was significantly reduced as compared with that in virgin rats. These changes were also significant by an analysis of variance. There was no significant difference in methylglucose transport activity between lactating and nonlactating groups. Basal glucose transport

activity was slightly reduced in the muscle pieces from rats on day 20 of pregnancy and on days 4 and 9 post partum with lactation.

Insulin-binding activity (Fig. 2). Insulin-binding activity was significantly increased in the muscle pieces from rats on days 1 and 4 post partum with or without lactation as compared with that in virgin rats. These changes also were significant by an analysis of variance. There was no significant difference in insulin-binding activity between lactating and nonlactating rats.

Comment

Skeletal musle is a major tissue that is responsible for peripheral insulin resistance.² However, studies on pregnancy-induced insulin resistance in isolated skeletal muscle are limited. We think isolated epitrochlearis muscle is suitable for this purpose because it is easily removed, thin, and adequately oxygenated.¹⁴ It is more sensitive to insulin than other muscle tissues, such as soleus or extensor digitorum longus, and has a large glucose utilization.¹⁵ The results of our basic experiments on epitrochlearis muscle strips that showed unchanged adenosine triphosphate levels during the transport experiments, a linear uptake of methylglucose in the time course, and saturable insulin-binding activities indicate its applicability in the current study.

Among the characteristics of the animals, a slight but significant decrease in serum insulin concentrations on day 20 of pregnancy seems inconsistent with the previous reports, which demonstrated increased¹⁶ or unchanged^{2, 8} insulin levels in rats during late pregnancy. However, there are also researchers¹⁷ who observed decreased insulin levels in rats near term. The reason for this discrepancy is not clear, but we think one of the causes may be a difference in the time of experiment. Because of the large consumption of glucose by the fetal pups in rats, the blood glucose levels in the mother are considerably lowered in a fasting

state, namely, during daytime for rats. This markedly low glucose level caused by fetal glucose use may lead to decreased maternal insulin concentration, even if insulin resistance exists in the maternal insulin-sensitive tissue.

The decrease in insulin-stimulated methylglucose transport activity in isolated skeletal muscle on day 20 of pregnancy is in accordance with our previous data in isolated adipocytes. Our findings of in vitro insulin resistance during late pregnancy and the postpartum

period also are in accordance with in vivo findings with the glucose clamp technique.2, 18 The reason for the discrepancy between the data in isolated soleus muscle11 and ours in isolated epitrochlearis muscle is not clear. The effect of insulin on glucose use in soleus and epitrochlearis muscle seems somewhat different according to the previous report¹⁸ on the basis of the glucose clamp technique. Therefore one of the reasons may be a difference in the muscle tissue used. It might be difficult by soleus muscle in vitro to detect a rather small difference in glucose transport activity between pregnancy and nonpregnancy.

Reports on insulin-binding activity in tissues or cells other than skeletal muscle during pregnancy indicate it is increased19 or unchanged,8,20 although a few authors observed a decrease.21 There are relatively few reports on insulin binding after parturition.22 They show unchanged insulin-binding activity at least during the early postpartum period. The insulin-binding activity in isolated skeletal muscle in our experiments was unchanged during pregnancy, was increased during the early postpartum period, and had returned to normal by day 9 post partum. Considering all these reports, changes in insulin-binding activity do not appear to induce insulin resistance around parturition, which means that insulin resistance around parturition is derived from changes in the intracellular process after insulin binds to its receptors.

There is much controversy on insulin resistance during lactation. Some researchers²³ claim that prolactin induces insulin resistance, but others24 do not. Insulin resistance in peripheral tissues in lactating rats has been observed, although the rate of glucose use for the whole body is increased.18 We could not find any significant difference in insulin-stimulated methylglucose transport activity between lactating and nonlactating rats. Our results suggest that lactation does not play a major role in developing insulin resistance during the postpartum period.

In general, low or normal insulin and glucose concentrations may be thought to contradict insulin resistance because typical insulin-resistant diseases such as obesity or insulin-resistant diabetes usually show hyperinsulinemia and hyperglycemia. However, hypoinsulinemia and hypoglycemia are also observed in some insulin-resistant states such as starvation.25 Therefore we think low or normal insulin and glucose concentrations during late pregnancy and the postpartum period in our data do not contradict peripheral insulin resistance. The teleologic meaning of insulin resistance in maternal peripheral tissues during pregnancy is sparing glucose for the fetuses and the maternal brain, which are dependent on glucose as an energy source. The meaning of insulin resistance during the postpartum period seems more complicated. There must be some organ or tissue that requires and consumes glu-

cose spared by the insulin-sensitive tissues. One candidate is the mammary gland, but our data suggest that lactation is not a major determinant of insulin resistance during the postpartum period. It remains to be clarified, but we speculate that insulin resistance in the peripheral insulin-sensitive tissues may be required to spare glucose to restore the depleted glucose storage in the liver or other tissues during the postpartum period.

The effects of electric field-mediated transfer of nonpermeable molecules of meiosis, fertilization, and early embryo development

James W. Douglas, MD, Fred A. Miller, MS, and Moon H. Kim, MD

Columbus, Ohio

Currently there is no simple method of introducing nonpermeable molecules into oocytes or embryos. A technique that would allow direct access to the cytosol with minimal cell damage would be an extremely useful tool in gamete and embryo research. This study investigates the use of electric field—mediated transfer of nonpermeable molecules into mouse oocytes and embryos. Meiosis II stage oocytes, pronuclear stage zygotes, and two-cell embryos were used to determine optimal voltage settings needed for molecular transfer, viability, and blastocyst transformation in culture. Our highest voltage setting (7.0 kV) yielded molecular transfer, viability, and blastocyst transformation rates of 68%, 73%, and 46%, respectively, in two-cell embryos, whereas our lowest setting (3.75 kV) yielded rates of 28%, 90%, and 47%, respectively. Blastocyst transformation rates for control embryos not exposed to the electric field were significantly higher at 69% (p < 0.01). Melosis, as assessed by germinal vesicle breakdown, was not affected when compared with controls, 78% versus 83%, respectively. We conclude that electric field—mediated transfer of nonpermeable molecules into oocytes and embryos is a simple, relatively atraumatic technique that can be used to study intraoocyte physiologic characteristics and embryo development. (AM J Obster Gynecol 1991;165:1480-6.)

Key words: Electric field—mediated transfer, oocytes, embryos, blastocyst transformation, germinal vesicle breakdown

Gamete and embryo research is hindered by our inability to gain access to the cytosol and nucleus in a simple, atraumatic fashion. Many of the regulatory

mechanisms of meiosis, fertilization, and embryo development are unknown or poorly understood. A tool that would allow us to monitor biologic effects after introduction of specific proteins, nucleic acids, or antibodies directly into these cells would greatly enhance our ability to understand intracellular physiologic characteristics and control mechanisms. Currently, the method of choice for introducing nonpermeable molecules into oocytes is microinjection. This process, however, is technically difficult, time-consuming, and often traumatic.

1

Recently we have shown that electric field-mediated transfer of enzymes is a simple, efficient method of transferring functional enzymes into human oocytes with minimal cellular damage.1 However, if it is to be used in gamete and embryo research, its effect on meiosis, fertilization, and embryo development must be fully examined. Therefore experiments were designed to answer the following questions:

- 1. Can nonpermeable molecules be transferred into mouse oocytes and embryos without adversely affecting viability, meiotic maturation, fertilization, or blastocyst development?
- 2. When is the optimal time to perform electric field-mediated transfer, i.e., oocyte, zygote or
- 3. What effects on molecular transfer, blastocyst transformation, and viability are seen when the electric field strength is altered?

Material and methods

Oocyte and embryo collection. Four different cell types were investigated: germinal vesicle stage oocytes, meiosis II metaphase stage oocytes, pronuclear stage zygotes, and two-cell embryos. Oocytes and embryos were collected from immature C57BL6-SJLF1 mice (Jackson Labs, Bar Harbor, Me.) Institutional guidelines for care and use of animals were fol-

Superovulation was initiated by intraperitoneal injection of 5 U of pregnant mare's serum gonadotropin (Sigma, St. Louis). Forty-eight hours later 5 U of human chorionic gonadotropin (Sigma) was given intraperitoneally. Fifteen hours later the mice were killed by cervical dislocation, and the oviducts were surgically removed into phosphate-buffered saline solution (Irving Scientific, Irving, Calif.). Cumulus masses were then collected by incising the oviduct with a 25-gauge tuberculin syringe needle. They were placed in a dish of phosphate-buffered saline solution and randomly separated into the various experimental or control groups. All results are collective results from at least seven female mice for each set of results. Cumulus masses containing pronuclear stage zygotes were collected from superovulated immature female mice mated to adult male mice of verified fertility. Meiosis II stage oocytes were collected from superovulated nonmated mice. Two-cell embryos were obtained by incubating pronuclear stage zygotes for 24 hours in Whitten's media containing 3 mg/ml crystalline bovine serum albumin (ICN Biochemicals, Cleveland) in 5% carbon dioxide, balance air, 37° C, and 99% relative humidity.

Germinal vesicle stage oocytes were collected 48 hours after the initial pregnant mare's serum gonadotropin injection. They were obtained by individual follicular puncture of surgically removed ovaries.

Oocytes and zygotes were immediately transferred

to Whitten's media and incubated at 37° C in a 5% carbon dioxide, humidified environment.

Settings used for electric field-mediated transfer. Electric field-mediated transfer was accomplished with a Baekon 2000 gene transfer system (Baekon, Inc., Saratoga, Calif.). Up to 25 oocytes were placed in a Baekon receptacle containing 30 µl of Whitten's media along with the protein or dye to be transferred. The following three settings were used to determine the optimal electric field setting for protein transfer, blastocyst transformation, and viability:

- Setting A. 3.75 kV, 28 pulses, 1.6-second burst time, six cycles, 120-microsecond pulse width
- Setting B. 5.0 kV, 28 pulses, 1.6-second burst time, four cycles, 120-microsecond pulse width
- Setting C. 7.0 kV, 28 pulses, 1.6-second burst time, three cycles, 120-microsecond pulse width

Application of the electric field took <1 minute. The oocytes were immediately washed three times in phosphate-buffered saline solution and returned to the 5% carbon dioxide incubator in Whitten's media. After incubation the oocytes were examined.

Assessment of enzyme transfer. Oocytes and embryos were subjected to electric field-mediated transfer on setting C in Whitten's media containing 1 mg/ml of the enzyme horseradish peroxidase (Sigma). After washing three times in phosphate-buffered saline solution, the cells were fixed in 2.5% glutaraldehyde in phosphate-buffered saline solution. The enzyme substrate 3,3'-diaminobenzidine (Sigma) and 0.01% hydrogen peroxide was then added. The cells were mounted on slides and examined with phase contrast and confocal microscopy (Biorad, Cambridge, Mass.) for the presence of intracellular brown precipitate characteristic of the horseradish peroxidase-3,3'-diaminobenzidine-hydrogen peroxide reaction.1 These results were then compared with those obtained with lucifer yellow transfer on setting C. This was done to determine if the two methods of assessing transfer yielded similar results.

Controls to rule out possible endogenous enzyme substrate and endogenous peroxidase activity were run simultaneously with the experimental group. These controls were performed by excluding either the enzyme substrate (3,3'-diaminobenzidine-hydrogen peroxide) or the enzyme (horseradish peroxidase), respectively. Also, to rule out endocytosis, the cells were incubated in 1 mg/ml of horseradish peroxidase for 20 minutes without going through electric field-mediated transfer. These cells were then fixed and the substrate 3,3'-diaminobenzidine-hydrogen peroxide was added.

Assessment of Lucifer yellow transfer. A 1 mg/ml concentration of the fluorescent dye lucifer yellow (Sigma) in Whitten's media was used for electric fieldmediated transfer on each of the three sections (A, B,

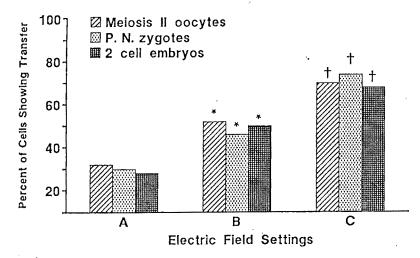

Fig. 1. Percentage of meiosis II oocytes, pronuclear zygotes, or two-cell embryos that showed evidence for molecular transfer of lucifer yellow dye after electric field-mediated transfer on setting A, B, or C. Asterisk, p < 0.01 when A compared with B; dagger, p < 0.01 when B compared with C. P.N., Pronuclear.

and C). After this procedure the cells were washed six times in phosphate-buffered saline solution, mounted on slides, and assessed for dye transfer with the use of fluorescence microscopy as described by Mir et al.2 Control oocytes were incubated in 1 mg/ml of lucifer yellow for 2 minutes, washed six times in phosphate-buffered saline solution, and compared with the oocytes that had undergone electric field-mediated transfer.

Assessment of germinal vesicle breakdown after electric field-mediated transfer. Germinal vesicle stage oocytes underwent electric field-mediated transfer on setting C. They were then incubated for 6 hours in a 5% carbon dioxide environment at 37° C. Light microscopic determination of germinal vesicle breakdown was then compared with control oocytes that had not been subjected to electric field-mediated transfer.

Assessment of viability after electric field-mediated transfer. Oocytes and embryos underwent electric field-mediated transfer on setting A, B, or C and were then incubated for 24 hours. After incubation they were placed in 10 µg/ml of the vital dye rhodamine 123 for 3 minutes and washed three times in phosphate-buffered saline solution. Fluorescence microscopy was used to assess incorporation of rhodamine 123 into mitochondria.3 These were compared with controls that had not undergone electric field-mediated transfer.

Assessment of fertilization and blastocyst transformation after electric field-mediated transfer. To assess the effects of electric field-mediated transfer on fertilization, meiosis II stage oocytes underwent the procedure at setting A, B, or C followed within 10 minutes by in vitro insemination with epididymal sperm. Fertilization rates for settings A, B, and C were compared with those of controls that had not under-

gone electric field-mediated transfer or had undergone electric field-mediated transfer without insemination (i.e., parthenogenetically activated oocytes).

Blastocyst transformation from in vivo and in vitro fertilized pronuclear stage zygotes and two-cell embryos after electric field-mediated transfer were assessed for all three settings and compared with simultaneously run controls that had not undergone electric field-mediated transfer.

Statistics. χ^2 Analysis of all groups was performed. The Bonferroni adjustment was used because multiple comparisons were analyzed for each group of data.4

Results

Molecular transfer rates. Lucifer yellow and horseradish peroxidase were used to determine the molecular transfer rate after electric field-mediated transfer on setting C. Transfer of the enzyme horseradish peroxidase with subsequent addition of 3,3'-diaminobenzidine-hydrogen peroxide yielded a dark brown precipitate within 64 of 90 (71%), 47 of 64 (73%), and 71 of 106 (67%) of meiosis II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively. The difference between those groups was not significant. Intracellular fluorescence after lucifer yellow transfer was seen in 60 of 85 (70%), 60 of 81 (74%), and 54 of 80 (68%) for meiosis II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively (not significant). Since horseradish peroxidase and lucifer yellow transfer rates were similar and lucifer yellow provided a direct means for evaluating transfer, it was used for the majority of the molecular transfer experiments. The results are shown in Fig. 1. With setting B the number of cells that showed dye transfer was 50 of 97 (52%), 44 of 95 (49%), and 45 of 94 (48%) for meiosis

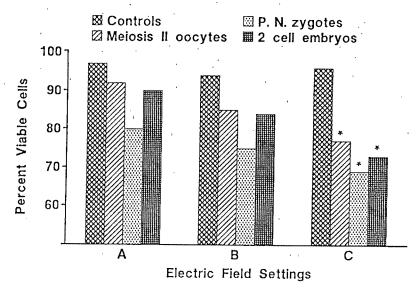

Fig. 2. Percentage of controls, meiosis II oocytes, pronuclear zygotes, or two-cell embryos that were viable after electric field-mediated transfer on setting A, B, or C. Asterisk, p < 0.01 when setting A, B, or C is compared with controls. P.N., Pronuclear.

II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively (not significant). With setting A the number of cells that showed dye transfer was 24 of 75 (32%), 21 of 70 (30%), and 22 of 78 (28%) for meiosis II stage oocytes, pronuclear zygotes and two-cell embryos, respectively (not significant).

It was noted in all our transfer experiments that when dye of enzyme transfer occurred in a two-cell embryo, both cells contained the transferred macromolecules. We also noted that control oocytes and embryos that had not undergone electric field-mediated transfer but were incubated in horseradish peroxidase or lucifer yellow did not show evidence of molecular transfer.

There was a statistically significant increase in molecular transfer when setting A was compared with B and setting B was compared with C (p < 0.02).

Viability after electric field-mediated transfer. The results of our viability testing 24 hours after electric field-mediated transfer are shown in Fig. 2. With setting A the number of viable cells was 60 of 62 (97%), 70 of 76 (92%), 85 of 106 (80%), and 65 of 72 (90%) for controls, metaphase II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively.

With setting B the number of viable cells following electric field-mediated transfer was 48 of 51 (94%), 61 of 72 (85%), 52 of 69 (75%), and 49 of 58 (84%) for controls, meiosis II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively.

With setting C the number of viable cells after electricfield-mediated transfer was 47 of 49 (96%), 46 of 60: (77%), 42 of 61 (69%), and 43 of 59 (73%) for controls, meiosis II stage oocytes, pronuclear stage zygotes, and two-cell embryos, respectively.

Only setting C had a significantly lower viability rate than the controls that had not undergone electric fieldmediated transfer (p < 0.01).

Germinal vesicle breakdown. The rate of germinal vesicle breakdown after electric field-mediated transfer on setting C was compared with that of controls. Germinal vesicle breakdown occurred in 80 of 102 (78%) of oocytes exposed to electric field-mediated transfer versus 79 of 95 (83%) of controls (not significant).

Fertilization rates after electric field-mediated transfer. It was noted that 85 of 157 (54%) of meiosis II stage oocytes exposed to the electric field without subsequent insemination developed into normalappearing two-cell embryos. The majority of these parthenogenetically activated oocytes were arrested at the two-cell stage. When the oocytes were inseminated after electric field-mediated transfer, 85 of 131 (65%) developed to the two-cell stage, but only 11% developed into blastocysts.

Blastocyst transformation after electric fieldmediated transfer. The transformation from two-cell embryos to blastocyst was evaluated after electric fieldmediated transfer in pronuclear stage zygotes and twocell embryos (Fig. 3). The blastocyst transformation rates for pronuclear stage zygotes on settings A, B, and C were 46 of 94 (49%), 36 of 78 (46%), and 31 of 69 (45%), respectively (not significant). Sixty-four of 88 (73%) control zygotes not exposed to electric fieldmediated transfer went from two-cell embryos to blastocyst, and this was statistically higher than all the experimental groups (p < 0.01).

Blastocyst transformation after electric field-me-

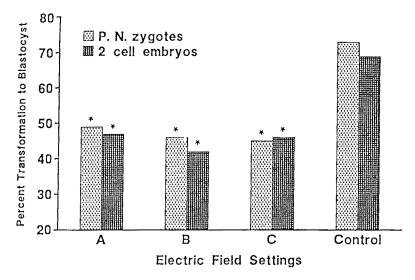

Fig. 3. Percentage of pronuclear stage zygotes or two-cell embryos that progressed normally from two-cell stage to blastocyst after electric field—mediated transfer on setting A, B, or C. Asterisk, p < 0.01 when pronuclear zygotes or embryos are compared with controls. P.N., Pronuclear.

diated transfer of two-cell embryos resulted in 79 of 168 (47%), 33 of 78 (42%), and 37 of 81 (46%) for settings A, B, and C, respectively (not significant). Fifty-two of 77 (68%) control two-cell embryos not exposed to electric field—mediated transfer transformed to blastocyst. The controls showed a significantly higher blastocyst transformation than all the electric field—mediated transfer groups (p < 0.01).

Comment

Electric field—mediated transfer evolved from the observation that cells could be induced to fuse when exposed to an electric field.⁵ This idea was modified to allow molecular transfer through permeation structures created by the electric field.⁶ The mechanism by which this works is unknown, but in theory, when an electric current is superimposed on the resting membrane potential, a critical threshold value is reached, at which point there is a dramatic and reversible increase in conductivity and permeability of the cell membrane. When the electric current is stopped, the permeation structures rapidly seal because of the fluid nature of the membrane, and the resting membrane potential is restored.

Until now almost all electric field—mediated transfer has involved deoxyribonucleic acid transfection and transformation in bacteria, plants, and other mammalian cell lines. Recently, we have expanded its use to the transfer of functional enzymes into human oocytes with an efficiency of 87% and a viability of 89%.

In this study we were able to show that transfer of the enzyme horseradish peroxidase into mouse oocytes can be accomplished in up to 73% of oocytes and that the functional activity of this enzyme is retained. The percentage of oocytes and embryos that showed molecular transfer varied depending on the electric field setting A, B, or C (Fig. 1). Higher voltage settings yielded higher transfer rates. This is in agreement with other studies using different cell lines.^{2, 10} The molecular transfer rate was similar for metaphase II oocytes, pronuclear stage zygotes, and two-cell embryos when the same setting was used.

Setting C was the original setting found to be suitable for transfer into mouse and human oocytes. Most of the adverse effects on viability are from increased voltage. Therefore the voltage was decreased for our new settings, A and B. We knew that lower voltage would have an adverse effect on the transfer rate. To compensate for this we increased the number of cycles to which the cells were exposed. It was hoped that this would maintain the same transfer rate as setting C and increase the viability. However, this was not the case. The lower voltage settings (A and B) had a lower transfer rate but did maintain a higher viability.

Meiotic maturation as assessed by germinal vesicle breakdown did not seem to be affected by electric field—mediated transfer; 84% of the controls and 79% of the oocytes showed germinal vesicle breakdown within 6 hours (not significant). Only setting C was used for this portion of the experiment because it was the most destructive in our viability testing and therefore most likely to have a detrimental effect.

Our test for viability used the vital dye rhodamine 123, which incorporates into mitochondria of living cells.³ As the voltage setting was increased, the viability decreased as shown in Fig. 2. However, only setting C showed a statistically significant decrease in viability when compared with that of controls. This decrease in

viability seen with high voltage has been reported by other investigators using different cell lines.2, 9, 10

Fertilization after electric field-mediated transfer was performed in vitro with meiosis II stage oocytes. We noted a 55% parthenogenetic activation rate when meiosis II stage oocytes were exposed to the electric field without subsequent insemination. When these meiosis II stage oocytes were inseminated after electric field-mediated transfer, 65% were at the two-cell stage 24 hours later. However, only 11% developed to blastocyst. These results suggest that the majority of oocytes that reach the two-cell stage probably were parthenogenetically activated and that some block to fertilization was present. Onodera and Tsunoda¹¹ recently reported similar parthenogenetic activation rates in mouse and rabbit oocvtes. Alterations in the cell membrane potential or an increase in intracellular calcium can cause parthenogenetic activation and subsequent release of the cortical granules. 12 This could explain the decreased fertilization potential of these oocytes after electric field-mediated transfer.

The transformation rate from two-cell embryos to blastocyst was evaluated in the pronuclear zygotes and the two-cell embryos after electric field-mediated transfer. Blastocyst transformation rates were similar for all three settings and for both cell types (i.e., two cell embryos and pronuclear zygotes). However, pronuclear stage zygotes and two-cell embryos both showed a statistically significant decrease in blastocyst transformation after being exposed to electric fieldmediated transfer when compared with controls (p < 0.01) (Fig. 3).

The enzyme horseradish peroxidase (40 kd) and the dye lucifer yellow (457 d) were used to evaluate molecular transfer. Horseradish peroxidase was used because it is not normally found in oocytes, and we wanted to determine if electric field-mediated transfer had any detrimental effect on the functional activity of an enzyme. The brown precipitate formed within the cells by the horseradish peroxidase-3,3'-diaminobenzidine-hydrogen peroxide reaction shows that the enzyme remained functional after electric field-mediated transfer.

Lucifer yellow transfer is an established technique in other cell lines and was used to confirm the results obtained with the horseradish peroxidase-3,3'-diaminobenzidine-hydrogen peroxide method that we developed.1,2 Similar results were obtained with both techniques (74% vs 73% molecular transfer for lucifer yellow and horseradish peroxidase, respectively, on setting C with pronuclear stage zygotes). Horseradish peroxidase and lucifer yellow are minimally permeable into mouse oocytes and embryos if left in solution for a long enough duration. In all of our electric field-mediated transfer experiments the cells were exposed to lucifer yellow or horseradish peroxidase for no more than 1 to 2 minutes. In this short amount of time no passive transport of these molecules is noted in control oocytes or embryos. This suggests than any lucifer yellow or horseradish peroxidase present within the cell has been actively transferred into that cell because of the electric field. There is nothing unique to the lucifer yellow or horseradish peroxidase molecules that enables them to be transferred more easily than any other molecules. Therefore introduction of other more significant molecules such as immunoglobulins to specific cell proteins or genetic material also can be performed with this technique. Currently we do not know the maximum molecular size that can be transferred into oocytes. However, a 150 kb linear, double-standard deoxyribonucleic acid has been electrotransfected into CV-1 cells.13 There are many biologic variables that affect electric field-mediated transfer such as field strength, pulse wave shape and duration, ionic concentration, pH, temperature, cell type, molecular configuration, and charge.10 A change of any of these variables can affect transfer rates and viability. It is therefore essential to carefully control for all these parameters.

Confocal microscopy was initially used to confirm the intracellular location of the precipitate formed by the horseradish peroxidase-3,3'-diaminobenzidinehydrogen peroxide reaction. This microscope, by the nature of its optics, enables the viewer to see thin sections (0.67 µm) of the specimen, similar to a computerized axial tomogram, thus confirming an intracellular location.

Since electric field-mediated transfer allows direct access to the cytosol, it potentially could be used to study intracellular physiologic characteristics, regulatory mechanisms, and cell replication in early embryos. Directing or controlling various oocyte or embryo functions is another possibility. Its role in the field of human reproduction is yet to be established, but it has been used to induce the acrosome reaction in human sperm and to transfer enzymes into human oocytes. 1, 14 In the future it could potentially be used to transfer genetic material into embryos diagnosed by embryo biopsy as having certain autosomal recessive or sex-linked disorders or for production of transgenic animals. It will be important to know if normal live offspring can be produced from embryos or oocytes exposed to electric field-mediated transfer. We assume that this is possible since we have shown that normal blastocyst development can occur after this procedure. Investigations are currently under way to confirm this.

In conclusion, electric field-mediated transfer can be used to transfer nonpermeable molecules into mouse oocytes, zygotes, and embryos. The molecules transferred into the oocytes remained functional. Increasing the electric field strength yielded a higher molecular transfer rate but a lower viability rate. Molecular transfer and viability were not dependent on the stage of the oocyte (i.e., metaphase II oocyte, pronuclear stage zygotes, or two-cell embryos). Meiotic maturation does not appear to be affected by electric field—mediated transfer. Blastocyst transformation after electric field—mediated transfer was not dependent on electric field strength but was statistically lower than that of controls. Electric field—mediated transfer of meiosis II metaphase oocytes causes a high rate of parthenogenetic activation and therefore significantly decreases in vitro fertilization rates. Electric field—mediated transfer is a simple, relatively atraumatic tool that can be used to study intracellular functions of oocytes and the developmental process of early embryos.

Forward shift in the initiation of the nocturnal estradiol surge in the pregnant baboon: Is this the genesis of labor?

Laird Wilson, Jr., PhD, Michael T. Parsons, MD, and George Flouret, PhD Chicago, Illinois, and Tampa, Florida

Daily (9 AM and 6 PM) blood samples were obtained from the inferior vena cava during the last trimester of pregnancy in a tethered baboon model. In addition, three 24-hour (hourly blood sampling) studies were performed at days 143 to 147, 158 to 162, and 172 to 177 of pregnancy. Dramatic 24-hour rhythms in progesterone and estradiol were detected, with both steroids surging nocturnally. Early in the third trimester the estradiol surge followed the progesterone surge. However, approximately 10 to 12 days before delivery, the initiation of the nocturnal estradiol surge shifted forward, thus preceding the progesterone surge. This forward shift in the estradiol surge created a daily (3 to 5 hours) window of elevated estradiol-to-progesterone ratio and appears to coincide with the initiation of nocturnal uterine contractions. The nocturnal uterine contractions can be inhibited by an oxytocin antagonist. We hypothesize that this forward shift in the initiation of the estradiol surge induces nocturnal uterine contractions by oxytocin release and/or increase in uterine oxytocin receptors and generates molecular messages that are the genesis for labor and delivery in the baboon. (AM J OBSTET GYNECOL 1991;165:1487-98.)

Key words: Estradiol, progesterone, uterine contractions, pregnancy, baboon

In nonprimate animals such as sheep, cows, goats, and rats parturition is preceded by a precipitate decrease in progesterone and a rise in estradiol in the blood. The increase in the estradiol/progesterone ratio can explain many of the changes that occur at delivery, such as an increase in uterine oxytocin receptor number, uterine prostaglandin production, and release of maternal oxytocin. In contrast, in primates such as humans, chimpanzees, hesus monkeys, and baboons, the ratio of estradiol to progesterone remains relatively constant through delivery.

The baboon is an excellent model for studying the endocrinology of human pregnancy because of its physiologic and anatomic similarity. The baboon has a hemochorial and monodiscoidal placenta and a fetal-placental unit in which the fetal adrenals contribute the major precursor for estrogen synthesis by the placenta. The one major dissimilarity in baboons from humans and great apes (gorilla, orangutan, and chimpanzee) is their inability to produce estriol. The major plasma estrogen is estradiol.⁶

6/1/30440

In this study we report the daily changes in plasma estradiol and progesterone throughout the last trimester of pregnancy and show that they have a significant 24-hour rhythm. Early in the third trimester estradiol and progesterone surge nocturnally, with the rise in estradiol following that of progesterone. However, as pregnancy progresses, the initiation of the estradiol surge shifts forward and precedes the progesterone surge by 3 to 5 hours. This shift in estradiol appears to coincide with the initiation of nocturnal uterine activity. Thus, although the ratio of plasma estradiol to progesterone over a 24-hour period does not change dramatically with increasing gestational age, a 3- to 5hour period develops where the ratio of estradiol to progesterone is elevated. We propose that this daily window of elevated estradiol/progesterone ratio initiates nocturnal uterine contractions by induction of biochemical alterations and generates other molecular messages that lead to labor and delivery.

Material and methods

Timed pregnant baboons (*Papio anubis*) from the breeding colony of the Biological Resource Laboratory at the University of Illinois were used in these studies. The animals were kept under controlled lighting conditions (12 hours light/12 hours dark) with lights on at 6 AM and fed food (Purina Primate Chow, fruit, nuts) once a day and water as desired. Normal delivery occurs at 184 ± 2 days. The protocol for this report has been approved by the Animal Care Committee at the University of Illinois.

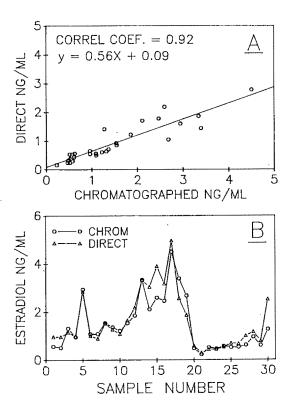

Fig. 1. Relationship between direct assay of estradiol in plasma samples by radioimmunoassay compared with prior extraction and chromatography of plasma. A, Correlation and leastsquares regression line between two assay methods for 30 plasma samples. B, Results of correcting direct assay data to 100% and comparing these answers with extracted-chromatographed samples. After correction results did not differ between two methods (p > 0.05).

The surgical procedure has been previously described in detail.7 Briefly, all baboons were operated on between 125 and 135 days of pregnancy. A midline abdominal incision was made to expose the uterus. Two 0.86×1.32 mm vinyl cannulas approximately 15 inches in length were inserted into the amniotic fluid by a 16-gauge needle acting as a trocar. The cannulas were exteriorized by a midlateral flank incision. A second incision was made in the groin area of the leg just above the external femoral vein and artery. Vinyl cannulas similar to those in the amniotic fluid were placed into each vessel so that the tip resided in the vena cava or aorta just above the bifurcation (approximately 8.5 inches in length). These cannulas, plus those from the amniotic fluid, were led subcutaneously to a middorsal area just inferior to the scapula. All skin incisions were closed with 2-0 Vicryl suture. A nylon mesh jacket (Alice King Chatham Medical Art, Los Angeles) was placed on the baboon, and the cannulas were led out through a flexible stainless steel tether attached to the back of the jacket. The tether, 24 inches in length, was attached to a punched-out training swivel on the side of the cage.

This technique allows the cannulas to be directly attached to pressure transducers and infusion pumps.8 The amniotic fluid cannulas were attached to P23id Gould pressure transducers, and pressure changes were recorded on a model 7 Grass polygraph (both from Grass Instruments, Quincy, Mass.). In addition, the analog signal was digitized with a Data Translation 2811H board on a Dell PC Limited 286 computer. The analog signal was sampled every second. The data were expressed as contractile force (Frequency × Mean amplitude) per 30-minute interval. The cannulas in the femoral vein and artery were attached to a syringe on a Harvard infusion pump. Heparin (100 U/ml) and cefazolin (71.4 mg/ml; Ancef, Smith Kline & French, Philadelphia) in saline solution were infused at a rate of 0.582 ml/hr to keep the cannulas patent and to deliver 1 gm/day cefazolin to the animals. After the first week the cefazolin was reduced to 0.5 gm/day.

Experimental protocol. Each day through delivery at 9 AM and 6 PM 10 ml of blood was withdrawn from the femoral vein cannula in five baboons. Blood samples were collected over ice and centrifuged at 4° C for 20 minutes at 2000 revolutions/min, the plasma was stored at -70° C until analysis. In addition to the daily samples, three 24-hour studies were performed at days 143 to 147, 158 to 162, and 173 to 177 in four of the five baboons. However, only one baboon was studied at day 175 since the other three delivered before this stage of pregnancy. Five milliliters of blood was collected every hour as described above for the daily samples.

Steroid radioimmunoassays. The radioimmunoassays for estradiol and progesterone have been previously described. 9, 10 Plasma progesterone was extracted with petroleum ether, evaporated, and assayed. Tritium-labeled progesterone was added at the beginning of the extraction procedure for estimating procedural losses, and all values have been corrected for such losses. The average recovery for the assay was 73% with intraassay and interassay variations of 5% and 6%, respectively.

Estradiol was measured directly in the plasma after the samples were diluted 1:5 in assay buffer. In preliminary studies the estradiol results were compared with those of a previously validated assay that consisted of ether-extracted, column-chromatographed plasma samples.10 The estradiol values from the direct assay of 30 diluted samples were 56% of those for the same extracted-chromatographed samples. However, the correlation coefficient of the estimated values between these two assays was 0.92 (Fig. 1, A) and was highly significant (p < 0.05). When the plasma estradiol levels were corrected for the 44% under estimation, the results closely compared with the extracted-chromatographed values (Fig. 1, B). No differences (p > 0.05)

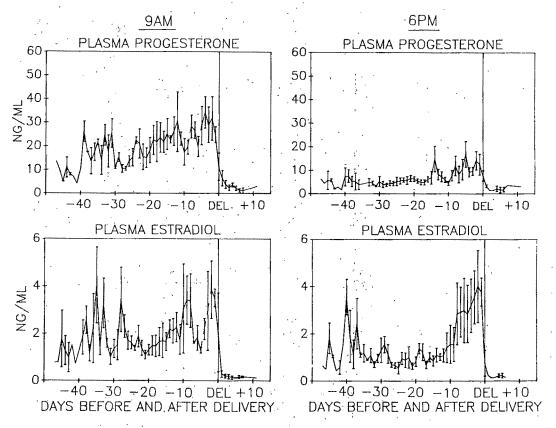

Fig. 2. Daily 9 AM and 6 PM progesterone and estradiol plasma levels adjusted to delivery during last trimester in pregnant baboons (n = 5; mean \pm SEM).

were detected when corrected values were compared by paired t test with the extracted-chromatographed values. Thus, although the values reported here are about 56% of the actual values, the patterns of variation are highly correlated with the actual values. The intraassay and interassay variations for this assay were 6% and 10%, respectively.

Statistical analysis. Data were analyzed by repeat analysis of variance, and, when significant, differences between means were detected by Tukey's test. In addition, the daily blood samples were analyzed by correlation and regression analysis. Finally, where appropriate, paired t tests were performed. ¹¹

Results

Changes in the daily 9 AM and 6 PM plasma estradiol and progesterone levels adjusted to the day of delivery in five baboons are illustrated in Fig. 2. There was substantial variation in the steroid levels during the first 10 to 15 days. This variation was due to the range in days during which the animals were operated on and to the effects of surgery on plasma steroids. Our study, plus that in the rhesus monkey, 12 show that progresterone and estradiol are elevated for 3 to 5 days after surgery. Thus, for the purpose of regression analysis only, the last 25 days before delivery was examined.

The correlation coefficient, regression equation, and level of statistical significance for the 9 AM and 6 PM progesterone levels versus the day of pregnancy before delivery were r = 0.29, y = 0.51x + 17.28, p < 0.007and r = 0.41, y = 0.38x + 3.73, p < 0.0001, respectively. Similarly, for the 9 AM and 6 PM plasma estradiol levels the results were r = 0.37, y = 0.074x + 1.138, p < 0.0003 and r = 0.54, y = 0.13x + 0.057, p < 0.00030.0001, respectively. The 9 AM plasma progesterone value was greater than the paired 6 PM value 91% of the time, and this was highly significant (p < 0.001) by paired t test. The estradiol levels showed more variation. The 9 AM values were greater than the paired 6 РМ value only 68% of time, and this was not significant (p > 0.05). Both progesterone (p < 0.001) and estradiol (p < 0.001) showed a significant effect of day of pregnancy in the repeat analysis of variance, and this is reflected in the statistically significant positive regression slopes.

Examples of plasma progesterone and estradiol levels in 24-hour studies in individual baboons are shown in Figs. 3 and 4. Fig. 3 shows the results of three 24-hour studies in a single baboon and compares changes in progesterone and estradiol to uterine contractile force (Frequency × Mean amplitude per 30 minutes) at 145, 160, and 175 days of pregnancy. There is a substantial

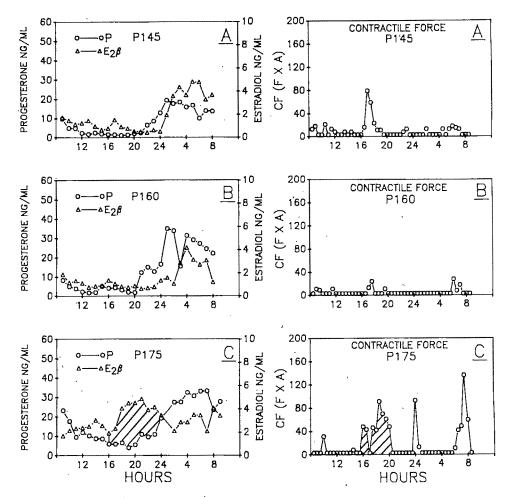

Fig. 3. Hourly fluctuations in steroids and contractile force over 24 hours at three stages of pregnancy in baboon 4953. At days 145 and 160 (A and B) progesterone surged nocturnally, followed by estradiol. However, at day 175 (C) initiation of estradiol surge shifted forward, preceding progesterone surge by 4 hours. Hour at which estradiol surge began coincides with initiation of nocturnal uterine activity (hours refer to 24-hour clock).

24-hour rhythm at each of the days studied, with progesterone and estradiol surging in the evening. At days 145 and 160 the estradiol surge follows the progesterone surge by several hours. However, by day 175 the initiation of the estradiol surge shifts forward so that it now precedes the progesterone surge by 3 to 4 hours. Coincident with this forward shift in the estradiol surge is the initiation of nocturnal uterine activity (Fig. 3, C).

Similar results are shown in another baboon in Fig. 4. At day 146 the nocturnal plasma estradiol surge follows the progesterone surge. However, at day 160 the initiation of the estradiol surge shifts forward and thus precedes the progesterone surge by 4 hours. This surge in estradiol coincides precisely with the increase in uterine contractile force activity. In this particular animal the uterine contractions were of such magnitude that an oxytocin antagonist produced in our laboratory, $^{7.13}$ [β -mercapto- β , β -cyclopentamethylene propionic acid,

D-Trp2, Phe3, Ile4, Arg8]oxytocin, was given as a single intravenous bolus injection of 3000 nmol to prevent delivery during the experiment. The oxytocin antagonist caused an immediate cessation in uterine contractions, but the estradiol surge appeared to be unaltered. No additional oxytocin antagonist was given, and this animal delivered spontaneously 7 hours after the completion of this study. The newborn was alive and appeared healthy and normal. The 24-hour experiment at day 175 could not be performed in this animal because of the delivery. The difference between the timing of the estradiol surges at day 160 of pregnancy in Figs. 3 and 4 represents the relationship of the day of pregnancy to delivery. The animal in Fig. 3 delivered at day 182; therefore day 160 was 22 days from delivery, which is before the shift in the estradiol surge would be expected to occur. In contrast, the baboon in Fig. 4 delivered hours after the end of the study on day 161.

In Figs. 3 and 4 the uterine activity at 12 midnight

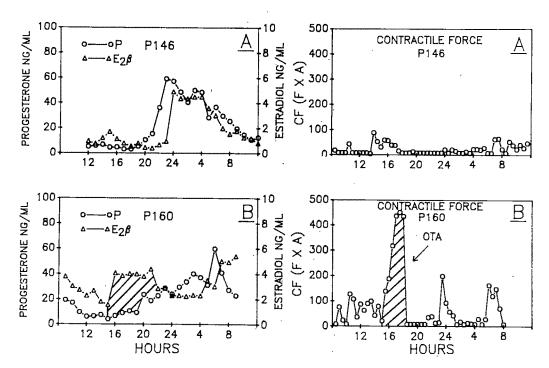

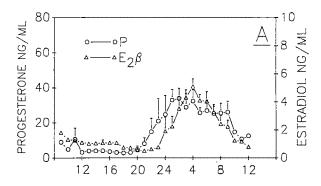

Fig. 4. Hourly fluctuations in steroids and contractile force over 24 hours at days 146 and 160 of pregnancy in baboon 4689. Similar to baboon 4953 in Fig. 3, forward shift in initiation of estradiol surge coincided with dramatic increase in uterine contractile force. Uterine contractile force was of such intensity that oxytocin antagonist (OTA), produced in our laboratory, was administered as a single bolus injection of 3000 nmol to prevent delivery during 24-hour study. Oxytocin antagonist caused immediate inhibition of uterine contractions, but estradiol surge was unaltered. This baboon delivered 7 hours after end of study (hours refer to 24-hour clock).

and 6 AM does not appear to correlate with the estradiol surge. However, the 12 midnight values are transient, particularly the one in Fig. 3 that consists basically of one point. The 12 midnight peak in Fig. 4 is slightly less transient, but it must be recognized that this animal was most likely in labor and that only the administration of the oxytocin antagonist prevented delivery. The uterine activity at 6 AM coincides with the turning on of the lights in the room (lights off at 6 PM and on at 6 AM). It is not unusual to see transient uterine activity related to this phenomenon or when the animals are fed, particularly if they are close to delivery. In addition, the plasma estradiol levels in the baboon in Fig. 4 remained elevated and appeared to be surging 6 AM; this might have contributed to the uterine activity at this time.

Fig. 5 summarizes the 24-hour studies for four baboons by comparing studies >10 days before delivery (Fig. 5, A) with those <10 days before delivery (Fig. 5, B). Both progesterone and estradiol showed significant diurnal variation (p < 0.001). The estradiol surge was statistically significant but the comparison of the 9 AM and 6 PM estradiol values (see above) was not, because the latter values represent time periods closer to the midday nadir in estradiol. It is the peak in the nocturnal estradiol surge that differs significantly from

the nadir in the afternoon samples. The data for these 24-hour steroid fluctuations were fitted to a tenth-order polynomial, and this resulted in correlation coefficients of >0.99 for all polynomials. First-order derivatives of these polynomials determined the rate of change of the plasma steroid levels and provided an estimate of the initiation and peak of these nocturnal surges. These data indicated that >10 days before delivery the estradiol surge follows the progesterone surge by about 3 hours. The progesterone surge begins about 7 PM and peaks at 2:30 AM the following morning. The estradiol surge begins at 10 PM and peaks at 4:30 AM the next day. In contrast, <10 days before delivery the initiation of the estradiol surge shifts forward 6 hours and precedes the progesterone surge by 2 to 3 hours. The estradiol surge being about 4 PM and peaks at 1:30 AM the next day. The progesterone surge begins at 6 PM and attains a peak at 5 AM the following day.

The 24-hour studies show a substantial amount of variation because of the different times when the estradiol and progesterone surges begin, the different levels of estradiol and progesterone in the plasma, and the small number of observations. Averaging together such data gives a misleading picture as to the characteristic shape and relationship of the estradiol surge to the progesterone surge. The estradiol surge has more

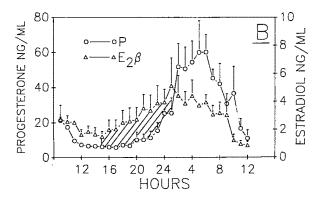

Fig. 5. Hourly fluctuations in steroids (mean \pm SEM) over 24 hours at >10 and <10 days before delivery. A, >10 days before delivery nocturnal estradiol surge followed progesterone surge. B, <10 days before delivery initiation of estradiol surge shifted forward and preceded nocturnal progesterone surge (N = 4; hours refer to 24-hour clock).

of a square-wave appearance (e.g., Figs. 3 and 4) when an individual baboon is examined. In an attempt to adjust for this variation the data were reanalyzed by comparing all values relative to initiation of the estradiol surge and examining the data ±6 hours of this surge. These results are shown in Fig. 6. The initiation of the estradiol surge (Figs. 5 to 7) was determined by calculating the first derivative for each time period by the use of n, n-1 and n+1 for the quadratic equation. The time period immediately preceding the first peak derivative past the midday nadir for plasma estradiol was considered time 0. If the derivative immediately preceding the peak derivative differed by no more than 0.03 (thus indicating a significant change), then the time period immediately preceding this hour was considered time 0. When expressed in this form, the mean estradiol surge appears more as a square wave. At >10 days before delivery the estradiol surge began 2 hours after the progesterone surge (Fig. 6, A), but at <10 days before delivery the initiation of the estradiol surge preceded the progesterone surge by 4 hours (Fig. 6, B). Thus the forward shift in the initiation of the estradiol surge compared with the progesterone surge was approximately 6 hours. Statistical analysis of these adjusted data indicated that both the progesterone and estradiol surges were significant (p < 0.01). Three of the four animals in the study showed a shift in the initiation of the estradiol surge of 4 to 5 hours compared with the start of the progesterone surge. In the fourth animal the initiation of the estradiol surge was advanced only about 1 hour. The fourth animal was 7 days from delivery, which was the maximum in time difference from delivery in the four animals in the study.

Similar to the steroid data, the contractile force was adjusted relative to the initiation of the estradiol surge; these results are shown in Fig. 7. The variation is very large because of the differences in contractile force between animals and the small number of animals studied. However, it can be seen that the rise in the contractile force coincides with the rise in estradiol. Of the four animals represented by these data, one was in labor, one showed no uterine contractile activity, and the other two had moderate activity.

Comment

Several important observations have been made in this study. First, the daily 9 AM and 6 PM progesterone and estradiol levels showed significant (p < 0.05) increases during the last 25 days before delivery, with the 9 AM progesterone and 6 PM estradiol levels showing the most dramatic increases. In addition, the 9 AM plasma progesterone level was higher (p < 0.05) than the 6 PM value 91% of the time. In contrast, no statistical difference in plasma estradiol levels was detected between 9 AM and 6 PM with advancing gestational age. The significant increase in plasma progesterone levels during the last trimester is in contrast to previous reports in the baboon,14,15 which suggested that progesterone reached a plateau by day 60 of pregnancy and remained constant until delivery. We believe this discrepancy in results can be explained by the time of day the blood samples were collected and is related to the 24-hour rhythm of plasma steroid concentrations (Fig. 5). In these previous reports a single daily blood sample was collected between 9 and 11 AM14 and 11 AM and 1 PM.15 Under the lighting regimen in our baboon colony these times would be close to the nadir in the progesterone surge (11 AM to 8 PM). The increase in the daily 9 AM plasma progesterone levels is more similar to that in humans2 than has been previously suggested from single daily blood samples obtained in the other baboon studies. 6, 14, 15 Considering the dramatic 24-hour rhythms in plasma progesterone and estradiol, variations in steroid levels as a result of single daily blood sampling in the baboon must be viewed with caution, since they may simply reflect shifts in the steroid surges

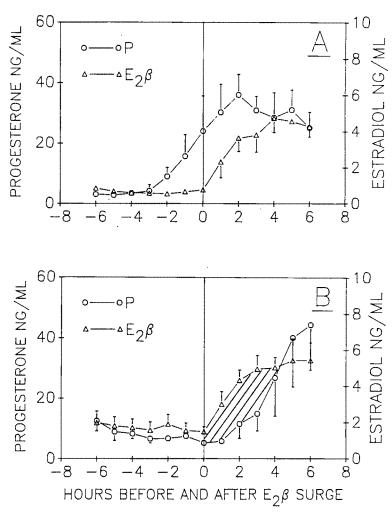

Fig. 6. Progesterone and estradiol in Fig. 5 were adjusted to initiation of estradiol surge and analyzed for 6 hours before or after this surge. When presented in this form, estradiol surge appears more as a square wave and reflects more accurately the characteristic appearance in individual baboons. Total shift in estradiol surge from >10 days (A) to <10 days (B) before delivery was about 6 hours (mean \pm SEM; N=4; hours refer to 24-hour clock).

and should not be perfunctorily interpreted as alterations in synthesis.

Similar to previous reports^{5, 14} in the baboon, significant increases in the daily plasma estradiol levels were seen during the last trimester. Most intriguing in this study was the rapid increase in the 6 PM plasma estradiol levels during the last 12 days before delivery. We believe this increase is related to the forward shift in the initiation of the estradiol surge into the time frame (6 PM) when the daily blood samples were collected. This increase in daily plasma estrogen during the last trimester is similar to reports for humans2 and rhesus monkeys.4

The second significant observation in this study is the identification of a 24-hour rhythm in plasma progesterone and estradiol during the last trimester of pregnancy. This has not been reported previously in the baboon except in abstract form. 16, 17 Plasma estradiol

and progesterone showed a significant 24-hour rhythm with nocturnal surges beginning between 7 and 10 PM and reaching peaks between 2:30 and 4:30 AM the next morning. Similar 24-hour rhythms have been reported in rhesus monkeys for progesterone and estradiol. 18, 19 However, in one study¹⁸ the estradiol rhythm was not statistically significant. In humans, 24-hour rhythms for estriol and progesterone were detected at 30 to 31 and 34 to 35 weeks of pregnancy but not at 38 to 39 weeks.20.21 In both human and rhesus monkey studies the incrementation from baseline to peak plasma steroid levels was not as great, and thus the differences not as evident, as in this study. There are several potential explanations for these differences. First is the site of blood sampling. The blood samples in this study were obtained from a cannula inserted in the inferior vena cava at a point past where the uterine veins empty.

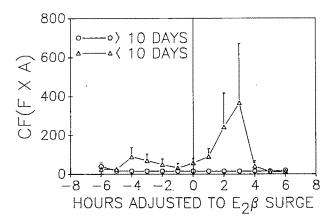

Fig. 7. Uterine contractile force adjusted to initiation of estradiol surge as represented in Fig. 6. Initiation of uterine contractile force <10 days before delivery coincided with initiation of estradiol surge (mean \pm SEM; N=4; hours refer to 24-hour clock).

Thus the progesterone and estradiol concentrations may reflect more the level of steroid hormones emanating from the uterus and to a lesser degree the results of peripheral metabolism, metabolic clearance, and dilution. In the human studies^{20,21} the blood samples were taken from the antecubital vein, whereas in the rhesus monkey reports¹⁸ the samples were from the aorta through a cannula placed in the femoral artery. We have performed 24-hour studies comparing aortavena cava differences in steroid levels (unpublished observations) in the pregnant baboon. Although the vena cava plasma steroid levels are often greater than the aortic concentrations, particularly for progesterone, substantial 24-hour rhythms are detected in both sources of blood. Thus this does not appear to be the only explanation for the more dramatic 24-hour steroid rhythms in this study, compared with those reported in the rhesus monkey and human. Second, species divergencies may contribute to the discrepancies in results. The progesterone and estradiol levels in rhesus monkey blood are much lower than in baboon and human blood. In addition, estriol, which is unique to humans and great apes, may have a role that is singularly important in these species. Finally, in the rhesus monkey reports18, 19 the studies were conducted earlier in pregnancy, when the maternal contribution of precursor to placental estrogen production is greater and may dilute the effect of fetal adrenal secretions on maternal estrogen levels, and the samples were collected less frequently (every 3 hours); thus the averaging of the values may abate the steroid rhythms by introducing more variation into the results.

In this study the timing in the initiation and peak of the steroid surges varies to some degree, compared with the rhesus monkey reports. The lighting regimen in the monkey studies was a cycle of 16 hours light/8 hours dark compared with this study of 12:12 hours. This may explain the dissimilarities in the timing of the peaks and valleys of the progesterone surge between these studies. Alterations in the light/dark cycle regimen have been reported to alter the timing of the nocturnal uterine activity and steroid hormone rhythms in the rhesus monkey.^{22, 23}

A rationale for the 24-hour rhythm in maternal plasma progesterone is less obvious than for estradiol. The precursor for placental progesterone is pregnenolone. It is possible that the fetal adrenals contribute to placental progesterone on activation of the fetal adrenals and increased pregnenolone secretion. Also, it is conceivable that the AM cortisol displaces progesterone from corticosteroid-binding globulin, contributing to enhanced clearance of free progesterone and consequently a reduction in plasma progesterone levels. There is evidence for this possibility. 19 A third explanation is that progesterone production may be dependent on estrogen. Administration of MER-25, an antiestrogen, to pregnant baboons reduced maternal progesterone by 50% and in vitro blocked the conversion of cholesterol to pregnenolone.24 Thus the rhythm in progesterone may be dependent on the estradiol rhythm. Finally, the metabolic clearance rate of progesterone appears to be influenced by cortisol, and this may contribute to the rhythm in progesterone levels.25 Obviously, further studies are required before a definitive explanation can be provided for the 24-hour rhythm in maternal progesterone. Clinically the recognition of the 24-hour rhythms in maternal plasma steroids might be important, for they suggest that assessment of fetal function and the fetal-placental unit dynamics may require obtaining at least two blood samples per day, one around midnight to 4 AM to establish the peak in the steroid surge and the other in the early afternoon (12 AM to 3 PM) for comparison with baseline values.

The third, and most important, observation in this study is the forward shift in the initiation of the nocturnal estradiol surge during the last 10 to 12 days of pregnancy, so that, unlike earlier in pregnancy, it precedes the nocturnal progesterone surge. This forward shift results in a period of 3 to 5 hours every day when the ratio of estradiol to progesterone is elevated, which seems to coincide with the beginning of nocturnal uterine activity. The observation that an oxytocin antagonist produced in our laboratory can inhibit this uterine activity (Fig. 2) without altering the pattern of the estradiol surge suggests that the surge is not dependent on enhanced uterine contractile activity but rather that enhanced uterine contractile activity might be dependent on the estradiol surge. In addition, these data indicate that oxytocin is a primary regulator of nocturnal uterine contractions, because of either an increase in oxytocin release, an enhanced uterine sensitivity to oxytocin, or both. We have previously reported that the oxytocin antagonist is a potent inhibitor of nocturnal and labor uterine contractions in the pregnant baboon.7 The data in this study suggest that estradiol is correlated with, and might be responsible for, the oxytocin effect. There are numerous reports in the literature indicating that estradiol is related to increased uterine activity12, 26 and can increase oxytocin release and uterine oxytocin receptor number. 27-29 Studies are in progress in our laboratory to determine the relationship among estradiol, oxytocin, and uterine contractions.

Although 24-hour studies in pregnant humans at different stages of pregnancy did not reveal a forward shift in the initiation of the nocturnal estradiol surge,20 close examination of this datum indicates a trend is present. For example, at weeks 34 to 35 the initiation and peak of the estriol surge occur about 4 hours earlier, compared with the estriol surge at weeks 30 to 31.20 A major difference between the human studies and this study is that the subjects examined at each stage of pregnancy in those experiments were not the same. This may have introduced more variation into those studies and obfuscated differences that might have been present.

The forward shift in the initiation of the estradiol surge also can explain the sharp increase in the 6 PM. plasma estradiol levels during the last 10 to 12 days before delivery (Fig. 2). We propose that this increase results from the forward shift of the estradiol surge into the time frame when the blood was withdrawn at 6 PM and is not only the result of an enhanced synthesis of estradiol. If this assumption is correct, then by examining the daily 6 PM samples for the initiation of the rise in estradiol in Fig. 2 the approximate time of the forward shift in the estradiol surge relative to delivery can be identified. Such a surveillance of our data suggests the forward shift in the estradiol surge occurs about 10 to 12 days before delivery.

The important implication of the forward shift in the nocturnal estradiol surge is that it provides a means of increasing the ratio of estradiol to progesterone without having a dramatic change in the synthesis or catabolism of these two steroid hormones. Thus we are hypothesizing that unlike nonprimate species, where the change in estradiol/progesterone ratio is achieved by decreasing progesterone and increasing estradiol production near term, a simple forward shift in the nocturnal estradiol surge results in an asynchronous 24hour rhythm of progesterone and estradiol. This shift provides a daily 3 to 5 hour window of elevated estradiol/progesterone ratio that is sufficient to induce molecular messages that initiate nocturnal uterine activity and ultimately lead to labor and delivery. This hypoth-

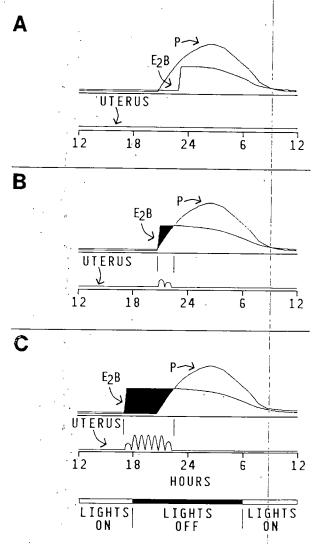

Fig. 8. Diagrammatic representation of hypothesis on initiation of nocturnal uterine activity. A, Early in third trimester progesterone (P) and estradiol ($E_2\beta$) show significant 24-hour rhythm with nocturnal estradiol surge following progesterone surge. With advancing gestational age (B and C) initiation of estradiol surge shifts forward and precedes progesterone surge. Coincident with estradiol shift is development of nocturnal uterine contractions. We propose that this forward shift in estradiol surge not only induces biochemical changes that result in uterine contractions but also initiates molecular messages that are the genesis for labor and delivery in the baboon (hours refer to 24-hour clock).

esis is summarized in Fig. 8. Another point to make is that the nocturnal activity is finite; that is, as the estradiol surge shifts forward and initiates uterine contractions, these contractions eventually terminate. We are proposing that the nocturnal uterine contractions are transient because of the nocturnal progesterone surge that blocks estradiol action at a critical threshold. Limited nocturnal uterine activity begins when the estradiol surge has shifted only slightly forward of the progesterone surge; thus the window of elevated estradiol and progesterone is small, and uterine contractions last for only a short period of time. As gestational age advances, the window becomes larger and the contractile activity lasts longer.

The hypothesis suggests that the surge in estradiol either prompts an immediate (within 1 hour) release of oxytocin and/or an increase in uterine oxytocin receptors or induces changes that are expressed 24 hours later. If estradiol action is immediate, it must not be acting by the classical genomic pathway for receptor action, which should take hours to initiate events that result in expression of cellular messages. Recent data suggest that progesterone may act nongenomically,30,31 and perhaps estradiol has similar effects. Catechol estrogens act on cell membranes similar to the way catecholamines do. Estradiol can be converted to catechol estrogens at the level of the hypothalamus32 and uterus,33 and perhaps it can enhance oxytocin release or increase the number of uterine oxytocin receptors. The second possibility is that estradiol acts genomically, and the response we observed results from an estradiol surge from the preceding 24 hours. Initial observations in our laboratory (unpublished observations) support the latter explanation. Also, this might explain why all animals did not show a one-to-one relationship between the shift in the estradiol surge and uterine contractions.

The cause of the forward shift in the nocturnal estradiol surge is not known. However, the literature provides a basis for at least a partial explanation. The fetal adrenal gland secretes increasing amounts of the estradiol precursor dehydroepiandrosterone sulfate with advancing gestation, particularly during the last 10 to 14 days. 18, 34 The fetal adrenals are under the control of corticotropin and other factors such as prolactin and growth factors.35 Fetal adrenal dehydroepiandrosterone sulfate secretion surges nocturnally; this correlates with nocturnal uterine activity.18 Cortisol or dexamethasone administered to pregnant humans or rhesus monkeys can eliminate nocturnal uterine activity and lower estradiol production by crossing the placenta and inhibiting fetal corticotropin release.36-38 In the pregnant rhesus monkey,18 human,39 and baboon6 maternal cortisol shows a 24-hour rhythm, attaining a peak around 6 to 10 AM. It has been proposed that as maternal cortisol decreases during the day, the negative feedback effect of cortisol on the fetal hypothalamicpituitary system diminishes, which in turn results in enhanced fetal corticotropin release and increased fetal dehydroepiandrosterone sulfate secretion and ultimately elevated placental estradiol production. Thus the fetal adrenal secretion of dehydroepiandrosterone sulfate would be 180 degrees out of phase with maternal cortisol.18 Advancement in the timing of the daily fetal adrenal activation could be due to a number of factors. A decrease in sensitivity of the fetal hypothalamic-pituitary axis to the negative feedback effects of maternal cortisol is one potential explanation. 40, 41 A second possibility is that adrenal secretagogues, such as prolactin (decidual or pituitary), or corticotropin secretagogues, such as placental corticotropin-releasing hormone or vasopressin, increase with advancing gestational age and enhance adrenal dehydroepiandrosterone production.35 Once the estradiol shift has begun, it could then increase the placental conversion of cortisol to cortisone, a biologically inactive corticosteroid. This has been demonstrated in the baboon placenta. 55 The decrease in maternal cortisol entering the fetus would further promote the advance in the nocturnal estradiol surge. Although this is only a hypothesis, it provides a rationale for the phenomenon of the forward shift in the initiation of the nocturnal estradiol surge. Additional studies will be required to definitively explain the forward shift in the estradiol surge.

The hypothesis suggests that the heightened estradiol/progesterone ratio induces uterine oxytocin receptor formation and increases production, or lowers the threshold of reflex activation for release, of hypothalamic oxytocin. However, the timing of oxytocin release is dependent on higher centers that are influenced by the light/dark cycles. 22, 28 Thus the increase in the estradiol/progesterone ratio is not only permissive in allowing oxytocin to be released and act on the uterus but perhaps obligatory for oxytocin synthesis. This is supported by observations in rhesus monkeys.26 In these studies fetal death was associated with a loss of nocturnal uterine activity coincident with diminished maternal estradiol levels. However, daily administration of estradiol benzoate by intramuscular injection to the mother reestablished the nocturnal uterine activity. Therefore this suggests that the purpose of the shift in the estradiol surge is to remove it from the inhibitory influence of progesterone, but the actual timing of the uterine activity is determined by higher centers that are influenced by the light/dark cycle. This hypothesis would also explain why the expression of the enhanced ratio of estradiol to progesterone takes about 24 hours. The increase in the estradiol/progesterone ratio only "sets the table" while the higher centers that are controlled by the light/dark cycle establish the precise timing of, and are the driving force for, the 24-hour rhythm of uterine activity. This part of the hypothesis is not supported by the human studies that report the loss of the estriol rhythm at term²⁰ but enhanced nocturnal uterine activity.42 Humans may be uniquely different in this respect, or the 24-hour rhythms in maternal estriol may still be present but not detectable in peripheral blood because of factors described above.

In summary, during the last trimester of pregnancy in the baboon the levels of estradiol and progesterone show a 24-hour rhythm, reaching baselines around 12 AM to 4 PM hours and surging nocturnally between 7 PM and 10 PM. As term approaches, the initiation of the nocturnal surge in estradiol shifts forward so that it precedes the progesterone surge. This shift in estradiol coincides with the beginning of nocturnal uterine activity. Since the nocturnal activity can be inhibited by an oxytocin antagonist, this suggests that oxytocin is a primary regulator of uterine contractions. Thus the surge in estradiol could either enhance oxytocin release, increase uterine sensitivity to oxytocin, or both. The precise timing of the oxytocin release is under the influence of higher brain centers. On the basis of these data we hypothesize that the forward shift in the initiation of the nocturnal surge of estradiol creates a daily window of increased estradiol/progesterone ratio that induces biochemical alterations (e.g., an increase in uterine oxytocin receptors or release of oxytocin) that result in nocturnal uterine activity and generate molecular messages that are the genesis for labor and delivery in the baboon.

We thank Joanne McNeal and Denis Almahdi for helping with the baboon surgery, Noelia Herrera and Russell Lindsey for collecting and analyzing the blood samples, and Irma Lopez for assistance in the manuscript preparation. Also, we acknowledge the Scientific Computer Workstation and the Biostatistics Facility of the Research Resources Center, University of Illinois at Chicago, which provided the equipment and assistance necessary to conduct these computations.

Measurement of human epidermal growth factor receptor in the endometrium during the menstrual cycle

Vladimir Troche, MD, Dennis M. O'Connor, MD, and R. Paul Schaudies, PhD Washington, D.C., and Bethesda, Maryland

To evaluate a potential physiologic role of the epidermal growth factor receptor in the endometrium, we measured the receptor content at different times in the menstrual cycle. Endometrial biopsy specimens were obtained from 28 normal women during the proliferative or secretory phase of the menstrual cycle, and the epidermal growth factor receptor content was determined. When the number of epidermal growth factor binding sites were evaluated as a function of time within each phase, a difference between phases became evident. The level of receptor increased during the proliferative phase with a maximum just before ovulation (p = 0.0128, r = 0.748). The epidermal growth factor receptor level decreased during the secretory phase, reaching a minimum before menses (p = 0.0001, r = 0.843). We conclude that the endometrial epidermal growth factor receptor content is cycle dependent, being maximal during the periovulatory period and minimal just before or during menses. These findings further suggest a physiologic role for epidermal growth factor in the proliferation and differentiation of the endometrium. (AM J OBSTET GYNECOL 1991;165:1499-503.)

Key words: Epidermal growth factor receptor, endometrium, menstrual cycle

Epidermal growth factor (EGF), a 53-amino-acid single-chain polypeptide, is a potent cellular mitogen for a variety of cell types.1 Studies of EGF administration in vivo or in vitro have been shown to result in accelerated proliferation and differentiation of a multitude of tissues of ectodermal origin.2 In vitro EGF administration results in increased cellular protein, ribonucleic acid and deoxyribonucleic acid synthesis, and enhanced cell multiplication.2 EGF exerts its biologic activity through interaction with specific transmembrane receptors, which have been found to be overexpressed in various human malignant tumors, such as squamous cell carcinomas of the head, neck, lung, and skin,3 and tumors of the thyroid,4 brain,5 breast,6 bladder,7 and colon.8 The presence of these abnormally elevated numbers of EGF receptors have been associated with more aggressive tumors and a poor prognosis. 6.7 This overexpression of the EGF receptor sugests a disrup-

tion of the normal regulatory mechanisms of cellular growth in which cell proliferation is controlled by regulation of the EGF receptor in the tissue.

The EGF receptor was identified in the human myometrium, endometrium, and leiomyomas. These findings support a role for EGF and its receptor in the proliferation and differentiation of the endometrium during the normal menstrual cycle. Research in this area has produced conflicting results, with no agreement as to the expression of the EGF receptor in the endometrium as a function of the menstrual cycle. EGF receptor content has been reported as follows: (1) being not different between the proliferative and secretory phases of the menstrual cycle, 10, 11 (2) being higher in the proliferative than the secretory phase, 12 and (3) exhibiting cyclic variation during the menstrual cycle.

We performed endometrial biopsies in 28 women of reproductive age at documented time points in the proliferative or secretory phase of the menstrual cycle. The endometrial tissues were assayed for the presence of the EGF receptor to investigate its expression in endometrium and establish a correlation for EGF receptor expression during the proliferative and secretory phases of the menstrual cycle.

Material and methods

Materials. Chloramine-T and Coomassie Brilliant Blue G were purchased from Sigma Chemical Company, St. Louis; minimum essential medium was obtained from Hazelton Biologics, Inc., Lenexa, Kan.; bovine serum albumin (fraction 5) was purchased from Gibco Laboratories, Grand Island, N.Y.; recombinant human EGF was supplied by Upstate Biotechnology,

Inc., Lake Placid, N.Y., and carrier-free sodium-iodine 125 was obtained from E.I. Dupont de Nemours & Co., Wilmington, Del.

Patients. The study population consisted of women of reproductive age undergoing diagnostic laparoscopy or laparoscopic tubal sterilization at our ambulatory surgery center. The human use committee of our institution approved the research protocol before patient recruitment started. The participants were recruited from the infertility and family planning services at Walter Reed Army Medical Center, Washington, D.C. They were taking no medications, and their menstrual histories were normal. Patients with amenorrhea, abnormal menstrual cycles, abnormal uterine bleeding, recent use of oral contraceptives (within the last 4 months), pelvic inflammatory disease, or pregnancy were excluded from this study. Before the scheduled surgery the research protocol was explained to all candidates, and informed consent was obtained from participants. On the day of the scheduled laparoscopic procedures, endometrial biopsies were performed with a Novak curette while the patients were under anesthesia. The biopsy specimens were taken in an uniform manner from the anterior, posterior, and lateral walls of the uterine fundus. A representative sample of each endometrial biopsy specimen was forwarded to our gynecologic pathologist for histologic dating, and the reminder of the biopsy specimens were immediately frozen in liquid nitrogen. The endometrial tissue was stored at -70° C until assayed. All participants were contacted within 2 to 4 weeks of surgery to document the date of onset of the next menstrual cycle. This information, together with the histologic results, was used to date the endometrial tissue.

Preparation of murine EGF and iodination of human EGF. Pure murine EGF was isolated by the method of Savage and Cohen.14 Recombinant human EGF was radioiodinated by the chloramine-T technique with carrier-free sodium-125I.15 The specific activity of the radiolabeled human EGF was adjusted to 1.5×10^6 counts/min/ng by the addition of nonlabeled human EGF.

Preparation of endometrial membranes. Endometrial tissues were homogenized in five volumes of icecold 10 mmol/L Tris hydrochloride, ph 7.5, containing 25 mmol/L sucrose and 1 mmol/L ethylenediaminetetraacetic acid with 15 slow strokes in a 7 ml Dounce homogenizer. The homogenates were centrifuged in a Beckman JA-20 rotor at 800 g at 4° C for 10 minutes. Nuclear pellets were discarded, and the resultant clear supernatants were centrifuged in a Beckman 60Ti rotor at 120,000 g at 4° C for 60 minutes. Supernatants were discarded and the resultant endometrial membrane pellets were resuspended in minimal essential medium containing 0.2% bovine serum albumin. The protein content of the resuspended membrane pellets was determined by the Bradford method,16 and the final endometrial membrane protein concentration was adjusted to 6 mg/ml.

Radioreceptor assay. This assay is based on the observation that nonlabeled EGF competes in an equimolar basis with radiolabeled EGF for the plasma membrane receptor and the fact that both murine and human EGF elicit nearly identical biologic responses.1,2

Binding assays were conducted in a total volume of 200 µl in 1.5 ml polyallomer microcentrifuge tubes. In all assays, 25 µl (150 µg) of endometrial membrane suspension was added to each tube. The binding reaction was initiated by the addition of 125I human EGF at nine separate concentrations ranging from 0.125 to 35 ng/ml to the microcentrifuge tubes. The incubations were performed in duplicate at room temperature for 90 minutes with gentle shaking. After incubation, 1 ml of ice-cold minimal essential medium containing 0.2% bovine serum albumin was added to each tube, followed by vortex blending. The tubes were immediately centrifuged in a Surespin centrifuge at 9500 g for 5 minutes. The supernatants were aspirated and the bound radioactivity in the pellets was counted in an LKB 1274 automatic γ -counter with a counting efficiency of 73%.

Specific binding was obtained from the differences between total and nonspecific binding that was determined in parallel in the presence of a 500-fold excess of nonlabeled murine EGF. Nonspecific binding accounted for 20% of the total binding. Scatchard¹⁷ plot analysis of the specific binding was performed for each endometrial membrane preparation, the number of binding sites, and the dissociation constant were determined. Statistical analysis of the data was performed by (1) the two-sample t test for independent samples, when the binding data of the proliferative and secretory phases were compared with each other and (2) simple linear regression, for evaluation of the binding data within each phase of the menstrual cycle.

Results

The participants in the study had a mean age of 30.2 years, with a range of 25 to 38 years. A total of 28 endometrial samples were obtained from these patients, 10 of which were in the proliferative phase and 18 in the secretory phase of the menstrual cycle. In Table I the participants in the study are divided according to the phase of menstrual cycle, and their characteristics are presented. The EGF radioreceptor assay was performed in all of these samples, and the EGF receptor content and dissociation constants were calculated for each endometrial sample and for each phase of the menstrual cycle. The binding of 125I human EGF to the endometrial membrane preparations was specific, because it was largely abolished by excess nonla-

beled murine EGF. The specific binding of 125 I human EGF also was saturable, with similar concentrations needed to attain saturation within each phase of the menstrual cycle. The calculated within-assay and between-assay variabilities for the EGF binding assay were 9.17% and 10.47%, respectively.

In the proliferative phase endometrium, the mean (±SEM) dissociation constant calculated from the individual K_d values obtained from the Scatchard plots was $8.80 \pm 3.10 \times 10^{-10}$ mol/L. The mean (\pm SEM) total number of EGF binding sites present in the endometrial membranes, as calculated from the binding data from each endometrial sample, was 24.56 ± 8.73 fmol/mg of protein, with a minimum and maximum number of 15.84 and 39.52 fmol/mg of protein, respectively. In the secretory phase endometrium, the mean (±SEM) dissociation constant calculated was $8.34 \pm 3.80 \times 10^{-10}$ mol/L, and the mean total number of available EGF binding sites was 24.31 ± 15.31 fmol/mg of protein, with a minimum and maximum number of 3.43 and 58.69 fmol/mg of protein, respectively. The mean K_d and mean number of EGF binding sites available in the membrane preparations from each phase of the menstrual cycle were compared with each other by means of the two-sample t test for independent samples. No significant differences were found between the proliferative and secretory phases in mean K_d values and mean number of EGF binding sites, with p = 0.74 and 0.96, respectively. These data are presented in Table II.

However, when the number of EGF binding sites was

evaluated as a function of time within each phase of the menstrual cycle, a difference between proliferative and secretory phases was evident. With advancing proliferative phase an increase in number of EGF binding sites was observed, which was maximal before the expected time of ovulation. Simple linear regression, performed with the EGF receptor content (number of EGF binding sites) of the endometrial membranes as the dependent variable and the proliferative phase day in which the sample was obtained as the independent variable, revealed a significant positive linear correlation with r = 0.748 and p = 0.0128 (Fig. 1). In the secretory phase the number of EGF binding sites was maximal at the beginning, decreasing with advancing secretory phase, being minimal before the time of expected menses. Simple linear regression performed with the EGF receptor content as the dependent variable and the secretory phase day as the independent variable revealed a very highly significant negative linear correlation with r = 0.843 and p = 0.0001 (Fig. 2). No significant linear correlation was seen between the dissociation constant and phase day in the proliferative and secretory phases of the menstrual cycle, with p = 0.99and 0.8, respectively.

Comment

Our study demonstrates the cyclic variation in endometrial EGF receptor content during the menstrual cycle as a function of time, confirming the previous report by Taketani and Mizuno.18 In addition, our data are in agreement with reports by Sheets et al.10 and

[†]Mean values ± SEM.

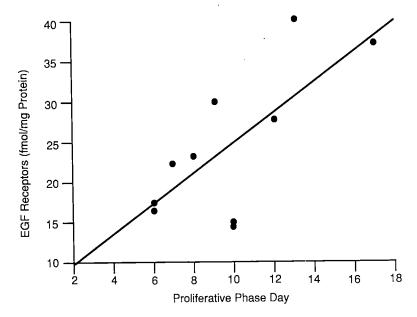

Fig. 1. Total number of EGF receptors as function of proliferative phase. Number of receptors is equal to number of binding sites as determined in Methods section. Significant positive linear correlation between EGF binding and advancing proliferative phase day was seen, p = 0.0128, r = 0.748.

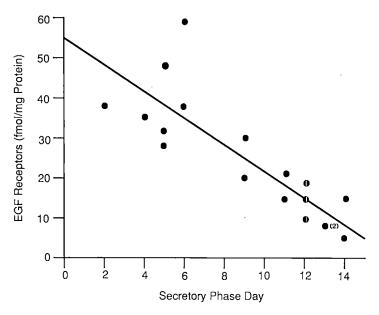

Fig. 2. Total number of EGF receptors as function of secretory phase. Number of receptors is equal to number of binding sites as determined in Methods section. Significant negative linear correlation between EGF binding and advancing secretory phase day was seen, p = 0.0001, r = 0.843.

Chegini et al.,11 in which mean EGF receptor contents of each phase of the menstrual cycle were found to be similar. Recently, Bonaccorsi et al. 12 published their results, which are in disagreement with these findings. They reported higher EGF receptor expression in endometrium of the proliferative as compared with the secretory phase. They used pooled endometrial membranes from 11 samples of proliferative and eight sam-

ples of secretory endometrium in their binding assays. To explain their results, we can only postulate that the endometrial samples were obtained late in the proliferative and secretory phases of the menstrual cycles. Then, on the basis of our findings, we would expect a higher receptor expression in the proliferative phase as compared with the secretory phase; these results are comparable to their findings.

During the menstrual cycle, the endometrium is characterized by cyclic changes of cell proliferation, differentiation, and death in response to sex steroids of ovarian origin. Although the exact mechanisms by which these changes take place are unknown, evidence is accumulating that implicates the regulation of growth factors and their respective receptors by sex steroid hormones. Most of the evidence being gathered originates from animal models. With these models, EGF and its receptor have been identified in uterine homogenates¹⁸ and uterine membrane preparations,¹⁹ respectively. In addition, the in vivo and in vitro effects of EGF and 17β-estradiol have been extensively studied. Administration of EGF, but not 17\u03c3-estradiol, to uterine epithelial cells in culture significantly stimulates cellular proliferation in a concentration-dependent manner.26 In vivo, 17β-estradiol administration results in an increase in uterine EGF receptor expression,21 which is preceded by an increase in uterine EGF receptor messenger ribonucleic acid.22

A hypothesis has been suggested to explain some of mitogenic effects of estrogen, in which estrogen promotes growth by regulating the levels of certain growth factors, such as EGF, or their receptors.²² Since estrogen action is the end result of binding to its high-affinity nuclear receptor, we can theorize that changes in their concentrations may affect the expression of EGF and its receptor in endometrium. During the menstrual cycle, as the estradiol concentration and estrogen receptor expression increase during the proliferative phase, a parallel increase in EGF receptor is seen. This increase is maximal during the periovulatory period, when the estradiol concentration and estrogen receptor expression also are at their maximum. After ovulation, progesterone secretion will result in a decrease in total estrogen receptor content and an increased endometrial metabolism of estradiol.23 As a result, even in the presence of high estradiol levels, with advancing secretory phase the EGF receptor content will decrease. This theory of estrogen regulation of EGF receptor expression in endometrium explains the cyclic variation in EGF receptor content seen during the normal menstrual cycle.

In summary, we have demonstrated the cyclic variation in EGF receptor expression during the menstrual cycle as a function of time and presented a possible mechanism by which estrogen and its receptor may regulate EGF receptor expression during the menstrual cycle. Although our findings give support to this theory of estrogen regulation of endometrial EGF receptor content, further studies are needed to elucidate the precise molecular mechanisms by which estrogens may regulate EGF receptor expression in endometrium.

Fetal cardiovascular and fluid responses to maternal volume loading with lactated Ringer's or hypotonic solution

David R. Powers, MD, and Robert A. Brace, PhDb

San Diego, California

To determine whether elevations in maternal vascular pressures or reductions in maternal osmolality would promote fluid transfer to the fetus, we intravenously infused either lactated Ringer's solution or diluted (hypotonic) lactated Ringer's solution continuously over 4 hours into late-gestation pregnant sheep. During the Ringer's solution infusion, the increases in maternal arterial (20.7 ± 1.7 mm Hg, mean ± SE) and venous (6.6 \pm 0.9 mm Hg) pressures were significantly greater (ρ < 0.00001) than those during the hypotonic infusion (6.6 \pm 1.5 and 1.7 \pm 0.6 mm Hg, respectively). The maternal osmolality changes during the Ringer's infusion (-5.7 ± 1.2 mOsm/kg at 1 hour and $+6.8 \pm 1.1$ mOsm/kg at 5 hours) were significantly less (p < 0.00001) than those during the hypotonic infusion (-10.2 ± 1.1 mOsm/kg at 1 hour and -15.9 ± 2.5 mOsm/kg at 5 hours). Fetal vascular pressures and blood volume were unchanged during either infusion. Fetal heart rate decreased by 15 to 20 beats/min by 1.5 hours of infusion in both groups but remained decreased only in the hypotonic group. Fetal urine flow decreased at the end of the Ringer's infusion and increased during the hypotonic infusion. These urine flow changes correlated with opposite changes in fetal plasma osmolality. The four-quadrant amniotic fluid index tended to increase in both groups, with an overall nonsignificant increase of 32% ± 16% 1 hour after the infusions. In summary, our findings suggest that (1) acute increases in maternal vascular pressures do not appear to promote fluid transfer to the ovine fetus and (2) acute decreases in maternal osmolality result in a small shift of fluid into the fetus as evidenced by an increase in fetal urine flow. (AM J OBSTET GYNECOL 1991;165:1504-15.)

Key words: Fetus, blood volume, urine flow, osmolality

Although it is clear that the human fetus accumulates 2 to 2.5 l of fluid from its mother during normal gestation, little is known to date about the mechanisms controlling this fluid transfer. If maternal factors are involved, from theory, the force(s) responsible could be either osmotic or hydrostatic pressure. There presently exists no clear understanding of whether physiologic alterations in one or both of these factors in the mother would lead to changes in fetal fluid balance. Previous animal and human studies have suggested that each may play a role. In terms of osmolality, it has been shown in animals and humans that induced increases or decreases in maternal osmolality are accompanied by similar changes in fetal osmolality. These osmolality changes in the fetus have been accepted to reflect

alterations in fetal fluid status even though (1) fetal volume changes have not been measured during reductions in maternal osmolality and (2) ovine fetal blood volume decreased only transiently during acute elevations in maternal osmolality and returned to normal within 1 hour. Furthermore, when pregnant ewes were subjected to several days of dehydration, no change from normal in fetal blood volume was found. Thus it is unclear whether fetal volume status actually varies with alterations in maternal osmolality within the physiologic range, although an extreme elevation in maternal osmolality has been shown to reduce the fluid volume of fetal rabbits.

The effects of variations in maternal hydrostatic pressures are similarly unclear. Animal studies have found no fetal fluid responses when isotonic fluid was administered to the mother.^{3,8} However, these previous studies are problematic because only small volumes were administered and maternal vascular pressures may have been unchanged. On the other hand, Goodlin et al.⁹ reported that pregnant women who were believed to have hypovolemia responded to oral or intravenous volume expansion with an increase in amniotic fluid volume. A recent case report by Sherer et al.¹⁰ gives futher credence to the suggestion that maternal volume expansion may increase fluid flux to the fetus. In that report a patient who presented with significant hypovolemia and severe oligohydramnios responded to

vigorous volume resuscitation (6500 ml fluid) with a normalization of the maternal volume status and amniotic fluid volume. Although the latter two studies suggest a role for maternal volume effects on the fetus, it is unclear whether changes in maternal vascular pressures or changes in osmolality provided the driving force for fluid transfer to the fetus, particularly in view of the fact that the maternal plasma sodium fell from 141 to 136 mEq/L in the latter study, suggesting that a reduction in osmolality may have been involved.

Because these observations do not provide a clear understanding of the effects of acute alterations in maternal hydrostatic or osmotic forces on fetal fluid dynamics, we evaluated whether fluid infused into pregnant sheep in sufficient quantities to elevate maternal venous pressure or reduce maternal blood osmolality would affect fetal fluid status. As indices of the latter, we determined fetal blood volume and composition, vascular pressures, urine output, and the four-quadrant amniotic fluid index.

Methods

Animal preparation. Seven gravid ewes with a gestational age (mean \pm SE) of 124 \pm 1 day at the time of surgery were used in this study. We followed university rules and regulations and United States Public Health Service guidelines for the care and use of laboratory animals. This protocol was approved by our institution's animal subjects committee.

With animals under gas inhalation anesthesia and with sterile surgical techniques, polyvinyl catheters were inserted in the fetal femoral arteries and veins, amniotic cavity, and urinary bladder as previously described.4,11,12 Polyvinyl catheters also were placed in the maternal inferior vena cava through a femoral vein and in the abdominal aorta through both femoral arteries for measurement of venous and arterial pressure and for blood sampling. A large-bore catheter was placed in the maternal inferior vena cava through the contralateral femoral vein for fluid infusion. The animals were maintained on a regimen of prophylactic antibiotics for the first 5 postsurgical days with daily flushing of the catheters with a heparin solution.12

Protocol. The first experiment was conducted 5 to 7 days after catheter placement while the ewe was maintained in a metabolic cart. In a random fashion, on days separated by at least 48 hours, the animals were infused intravenously with either lactated Ringer's solution (Baxter) or with lactated Ringer's solution diluted with sterile water to a final osmolality of 150 mOsm/kg. The experimental protocol consisted of a 1-hour control period, a 4-hour continuous infusion period, and a 1hour recovery period. All animals were subjected to at least one Ringer's and one hypotonic infusion. In the animals subjected to more than one Ringer's or hypotonic infusion, the volume of the infusate was purposely varied to explore a range of responses. A total of eight Ringer's and 11 hypotonic infusions was performed.

Experimental design. The objective of this study was to determine whether alterations in maternal hydrostatic or osmotic forces would promote fluid transfer to the fetus. For the hydrostatic portion of the study, we infused sufficient lactated Ringer's solution to elevate maternal venous pressure by 5 to 10 mm Hg. For the osmotic portion of the study, we infused sufficient hypotonic Ringer's solution (150 mOsm/kg) to reduce maternal osmolality by 3% to 10%. We refer to these as the Ringer's infusion and the hypotonic infusion, respectively. The rationale for infusing lactated Ringer's solution is that it is readily available and widely used. Although it is not exactly isotonic to normal blood (sodium, 130 mEq/L; potassium, 4 mEq/L; calcium, 3 mEq/L; chloride, 109 mEq/L; lactate, 28 mmol/L; measured osmolality, 255 mOsm/kg), we anticipated that the actual changes in maternal osmolality would be small. For the hypotonic infusion, the rationale for dilution of the Ringer's solution to 150 mOsm/kg was that this is the lowest osmolality that can be rapidly infused into the circulation and not cause extensive hemolysis.

Sampling and analytic measurements. At 30-minute intervals during the control period and 1-hour intervals thereafter, samples of maternal and fetal blood and urine and amniotic fluid were taken. The fetal blood samples (3 ml) were replaced with an equal volume of heparinized maternal blood drawn immediately before study. Electrolytes and osmolality were measured in all samples, and hematocrit and plasma protein concentration were determined in all blood samples. Fetal blood volume as a percent of that during the control period was calculated from fetal hematocrit with a correction for osmotically induced changes in red blood cell volume as previously described.4 This correction is important because hematocrit would be expected to increase when osmolality decreases, even though blood volume remains unchanged. Using this method, a 1% change in fetal blood volume can be detected with a 99% degree of confidence.4 The concentrations of arginine vasopressin and atrial natriuretic factor in fetal plasma samples were measured as previously described.13 Throughout the control, infusion, and recovery periods, fetal and maternal arterial and venous pressures and heart rates plus amniotic fluid pressure and fetal urine flow were recorded continuously on a polygraph recorder, digitized, and stored on disk at 30second intervals with an on-line computer as previously described.11 Fetal vascular pressures were corrected continuously with amniotic fluid pressure used as the zero pressure with the on-line computer The four1506 Powers and Brace November 1991

Table I. Fetal, maternal, amniotic, and urinary osmolalities and concentrations during 1-hour control period

Variable	Fetal blood	Maternal blood	Amniotic fluid	Fetal urine
Osmolality (mOsm/kg) Sodium (mEq/L) Chloride (mEq/L)	298.2 ± 0.9 141.1 ± 0.4 109.4 ± 0.3	300.9 ± 0.9 144.4 ± 0.5 113.5 ± 0.3	274.1 ± 9.1 115.1 ± 5.5 95.0 ± 4.3	228 ± 24 43.2 ± 5.1 41.3 ± 4.0
Potassium (mEq/L)	4.0 ± 0.1	4.4 ± 0.1	6.6 ± 1.0	11.7 ± 4.4

Values are mean ± SE.

Table II. Fetal values during 1-hour control period

Variable	Mean ± SE
Arterial pressure (mm Hg)	47.1 ± 1.1
Venous pressure (mm Hg)	3.8 ± 0.5
Heart rate (beats/min)	172 ± 3
Urine flow (ml/min)	0.47 ± 0.11
Arterial pH	7.336 ± 0.005
Carbon dioxide tension (mm Hg)	$54.5~\pm~0.5$
Oxygen tension (mm Hg)	21.0 ± 0.6
Hematocrit (%)	35.7 ± 0.9
Plasma protein (gm/dl)	4.0 ± 0.1
Amniotic fluid index (mm)	79.3 ± 11.7
Plasma arginine vaso- pressin (pg/ml)	3.9 ± 0.6
Plasma atrial natriuretic factor (pg/ml)	156 ± 13

quadrant amniotic fluid index was measured during the control and recovery periods as previously described. He Briefly, the uterus was divided into four quadrants that were scanned by ultrasonography. The amniotic fluid index equaled the sum of the largest vertical pocket of fluid in each of the four quadrants determined in triplicate.

Necropsy. After the experiments were completed, the animals were killed with a euthanasia solution (pentobarbital sodium, 300 mg/kg) and fetal weight was recorded.

Data presentation and statistical analysis. The data are presented as means \pm SEs. In some of the figures, the data are plotted as the mean \pm SE change from the average value during the control period.

We used an unpaired t test to compare values during the control period in the Ringer's infused compared with the hypotonic-infused animals. Because there were no statistically significant differences between the two groups, they were combined.

To determine whether there were statistically significant changes with time in each group, we used a two-factor repeated measures analysis of variance, with time and animal being the fwo factors. For comparing the Ringer's versus the hypotonic groups, we used a three-

factor analysis of variance, with time, treatment, and animal being the three factors. The interaction term from the latter analysis of variance was used to determine whether the changes in time in the two groups were statistically different. For exploring relationships among variables, bivariate and multivariate linear regression techniques were used. The symbols r and R are used to designate the bivariate and multivariate correlation coefficients, respectively. For the regression analyses, we used mean values during the control period and means during the last 1 hour of each infusion, expressed as changes from preinfusion values. Significance was taken as $p \le 0.05$ and described changes are significant at the $p \le 0.05$ level, unless specified otherwise.

During the data analysis, we found that the fetal urine flow rate response to the Ringer's or hypotonic infusion depended on the urine flow rate during the control period. Thus we arbitrarily chose to subdivide our experiments into those with basal fetal urine flows either above or below 0.5 ml/min. Fetuses with a urine flow rate <0.5 ml/min are referred to as the low-flow group and those >0.5 ml/min as the high-flow group. Normal urine flow rate for fetuses at the same gestational age in this laboratory averages approximately 0.6 ml/min.¹⁵

Results

Fetal gestational age on the day of experimentation in the Ringer's (130 \pm 2 days) and hypotonic groups (135 \pm 2 days) was not significantly different. Mean fetal and maternal values during the control period are shown in Tables I and II. These values are consistent with normal values from this laboratory.

During the control period, several variables were statistically related. Fetal osmolality correlated positively with maternal osmolality (r=0.855, $p<10^{-5}$). Fetal urine flow rate was positively related to fetal arterial pressure (r=-0.624, p=0.0045). Finally, amniotic fluid osmolality (r=0.620, p=0.0046) and urine osmolality (r=-0.603, p=0.0063) were negatively related to fetal urine flow rate.

During the volume loading with Ringer's solution to elevate maternal venous pressure, we infused 5.55 ± 0.50 L/hr for 4 hours into the maternal vein.

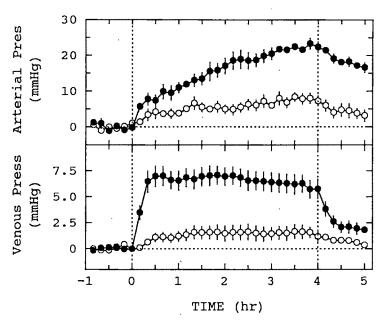

Fig. 1. Maternal arterial and venous pressure responses to Ringer's (dots) or hypotonic (circles) infusion into circulation of ewe. Data expressed as mean \pm SE change from average value during 1-hour preinfusion period. Vertical dotted lines show infusions started at 0 hour and ended at 4 hours.

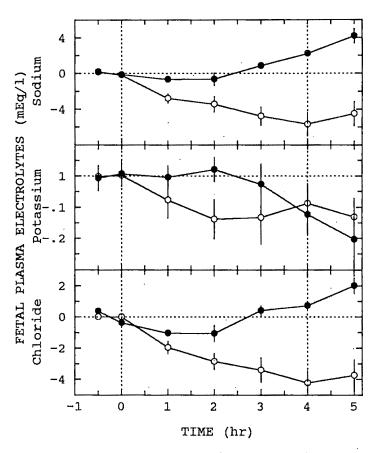

Fig. 3. Fetal plasma electrolyte concentration changes during Ringer's (dots) or hypotonic (circles) infusion into ewe's circulation. Data expressed as mean ± SE change from average value during 1-hour preinfusion period. Vertical dotted lines show infusions started at 0 hour and ended at 4 hours.

During the hypotonic infusion, 1.98 ± 0.29 L/hr were administered. The resulting changes in maternal arterial and venous pressures for the two different infusates are shown in Fig. 1. Maternal arterial and venous pressures were significantly elevated during both infusions (p < 0.00001) and the elevations were significantly greater during the lactated Ringer's infusion versus the hypotonic infusion (p < 0.0001). During the last 2 hours of the infusions, arterial and venous pressures were elevated by an average of 20.7 ± 1.7 and 6.6 ± 0.9 mm Hg, repectively, during the Ringer's infusion compared with 6.6 ± 1.5 and 1.7 ± 9.6 mm Hg during the hypotonic infusion.

Fig. 2. shows the infusion-induced changes in maternal osmolality. There were highly significant changes with time in both groups (p < 0.00001) and the decreases with the hypotonic infusion were significantly greater (p < 0.00001). Contrary to our expectations of a small, maintained decrease in osmolality over time in the lactated Ringer's group, maternal osmolality gradually increased after the initial decrease and was significantly above control at the end of the recovery period (p < 0.001). In the hypotonic group, maternal osmolality was decreased by $10.2 \pm 1.1 \text{ mOsm/kg}$ at 1

hour and gradually decreased further to 15.9 ± 2.5 mOsm/kg below control by the end of the infusion.

The fetal osmolality responses (Fig. 2) were highly significant (p < 0.00001) and paralleled the maternal responses (r = 0.946, p < 0.00001, during the last hour of infusion) but were slightly delayed and less in magnitude compared to maternal responses (analysis of variance interaction, p = 0.049 for hypotonic and p = 0.077 for Ringer's when comparing the fetal vs maternal osmólality changes). During Ringer's infusion, fetal osmolality initially decreased, followed by a gradual rise above preinfusion values at the end of the recovery period. In contrast, fetal osmolality decreased during the hypotonic infusion and remained reduced. These changes in fetal osmolality with time were significantly different (p < 0.00001) in the two groups. Fetal plasma electrolyte concentrations largely paralleled the changes in osmolality, as seen in Fig. 3. Fetal arterial pH increased by 0.03 units during the Ringer's infusion and was unchanged during the hypotonic infusion. Fetal carbon dioxide tension was unchanged during either infusion, whereas fetal oxygen tension was decreased only during the recovery period by an average of 1.8 mm Hg in both groups.

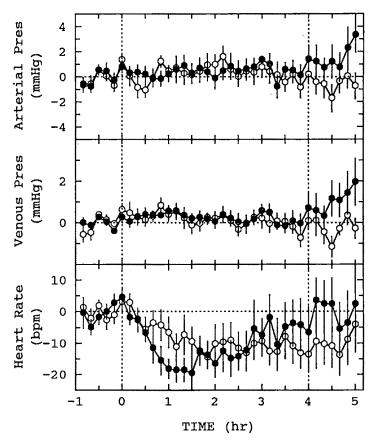

Fig. 4. Fetal vascular pressure and heart rate responses to Ringer's (dols) or hypotonic (circles) infusion into ewe. Data expressed as mean ± SE change from average value during 1-hour preinfusion period. Vertical dotted lines show infusions started at 0 hour and ended at 4 hours.

Fetal arterial and venous pressures were unchanged during either infusion, but there was a tendency for arterial and venous pressures to rise during the recovery period after Ringer's infusion (Fig. 4). Fetal heart rate initially decreased (p < 0.00001) by 15 to 20 beats/min in both groups (Fig. 4). During Ringer's infusion, fetal heart rate returned to control levels by the end of the infusion but remained reduced during the hypotonic infusion. These differences were highly significant (p = 0.0071). As seen in Fig. 5, fetal hematocrit decreased at the end of the 4-hour Ringer's infusion compared with an increase during the hypotonic infusion (p = 0.00020). Neither fetal plasma protein concentration nor the volume of blood circulating in the fetus underwent significant changes with time in either group (Fig. 5).

The fetal plasma arginine vasopressin and atrial natriuretic factor responses to the infusions depended on the infusate. As seen in Fig. 6, arginine vasopressin was unchanged during the Ringer's infusion, compared with a decrease averaging 20.9% ± 4.2% during the hypotonic infusion. Fetal plasma arginine vasopressin concentration increased above control in both groups at the end of the recovery period, and the overall

changes in arginine vasopressin with time in the combined groups were highly significant (p = 0.0004). Fetal plasma atrial natriuretic factor was unchanged during the hypotonic infusion (Fig. 6). Atrial natriuretic factor decreased by an average of 20 pg/ml during the isotonic infusion, but this was of marginal significance (p = 0.059).

Fetal urine flow rate underwent an increase during the hypotonic infusion; this was significantly different from the small increase, followed by a decrease, in urine flow rate during Ringer's infusion (p < 0.0001, Fig. 7). On closer inspection, we found that the fetal urine flow responses depended on the initial urine flow rate. That is, 2 hours after starting the Ringer's infusion, urine flow rate decreased in the fetuses with a high control flow, compared with no change with time in those fetuses with a low urine flow during the control period. Similarly, during the hypotonic infusion, fetal urine flow did not change in the animals with a high basal urine flow, but it increased significantly in the fetuses with a low basal urinary output. The changes in fetal urine flow during the last hour of the infusions correlated positively with the changes in fetal arterial pressure (p = 0.086), positively with the changes in fetal 1510 Powers and Brace November 1991

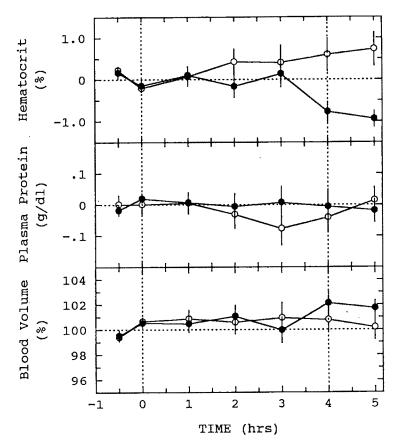

Fig. 5. Fetal hematocrit, plasma protein concentration, and blood volume responses to Ringer's (dots) or hypotonic (circles) infusion into the ewe. Data expressed as mean \pm SE change from average value during 1-hour preinfusion period for hematocrit and plasma protein concentration and as percent of control for blood volume. Infusions started at 0 hour and ended at 4 hours.

atrial natriuretic factor (p = 0.0053), and negatively with the changes in fetal blood osmolality (p = 0.0034), as determined by multivariate regression (R = 0.744; p = 0.006), but were not correlated simultaneously with the other variables.

Fetal urine composition was significantly altered during the infusions (Fig. 8). Fetal urine osmolality underwent a small transient decrease midway through the Ringer's infusion, followed by a rise above control levels. This was different (p < 0.00001) from the large decrease in urine osmolality during the hypotonic infusion. The changes in urine osmolality during the last hour of the infusion were inversely related to changes in urine flow (r = 0.865; p < 0.00001). Urine sodium and chloride changes paralleled the changes in urine osmolality, and differences in sodium and chloride between the two groups were marginally significant (p = 0.077 and p = 0.058 for Na⁺ and Cl⁻, respectively). There was no significant difference in fetal urine potassium between the two groups (p = 0.12).

Amniotic fluid composition underwent significant changes with time. Amniotic osmolality (Fig. 9) decreased with time (p = 0.0080), and the decrease in

the hypotonic group was only marginally different (p=0.111) from that during Ringer's infusion. Amniotic sodium and chloride concentrations paralleled the osmolality changes in that there were significant decreases with time (p=0.0121 and p=0.0105 for sodium and chloride, respectively), but the decreases during hypotonic infusion were not significantly greater than during Ringer's infusion. Amniotic potassium concentration did not change with time during Ringer's infusion but decreased during the hypotonic infusion. The amniotic fluid index tended to increase in both groups, with an overall increase of $32\% \pm 16\%$ I hour after terminating the infusions. These were not significant changes.

Comment

To better understand the extent to which acute alterations in maternal hydrostatic or osmotic forces may affect fetal fluid balance, we monitored the changes in fetal fluid and electrolyte status during short-term maternal volume loading in the pregnant ewe. We anticipated that either increasing the hydrostatic pressure or decreasing the osmotic pressure with volume loading

would result in significant force across the placenta to push fluid down a pressure gradient into the fetus. However, in spite of increases in maternal arterial and venous pressures of 20.7 and 6.6 mm Hg, respectively, during the Ringer's infusion, we found no increase in fetal arterial or venous pressures, blood volume, or urine flow. Collectively, these observations do not support the hypothesis that an increase in maternal vascular pressures will cause a significant transfer of fluid to the ovine fetus over a 4-hour period. It may be suggested that this is not surprising in view of the low value of the filtration coefficient that has been reported for the sheep placenta.16 However, in a recent study,17 we found a significatly higher value of the placental filtration coefficient such that at least 160 ml (i.e., 0.1 ml/min/mm Hg × 6.6 mm Hg × 240 minutes) may

have been expected to cross the placenta because of the changes in the hydrostatic pressure during our 4-hour infusion. In addition, it has also been shown that, when ovine fetuses were infused intravenously with 7 L of isotonic fluid over 3 days, five of the 7 L infused were transferred to the mother in the absence of any change in the fetal plasma composition.18 Thus it was surprising to see that a transfer of fluid to the fetal compartment was not evident during the Ringer's infusion. Furthermore, our observation of an actual decrease in fetal urine flow late in the infusion was unexpected but was consistent with theoretic considerations of the simultaneous increase in maternal osmolality. This late decrease in fetal urine flow suggests that either the concomitant rise in maternal osmolality had removed fluid from the fetus or that the associated rise in fetal os-

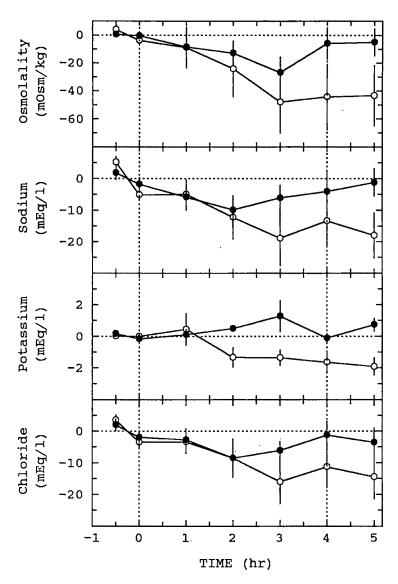

Fig. 9. Amniotic fluid compositional responses to Ringer's (dots) or hypotonic (circles) infusion. Data expressed as mean \pm SE change from average value during 1-hour preinfusion. Vertical dotted lines show infusions started at 0 hour and ended at 4 hours.

molality stimulated a late rise in fetal arginine vaso-pressin, which produced an antidiuretic effect. The latter mechanism is consistent with the observed changes in fetal arginine vasopressin concentrations and with the lack of change in fetal blood volume. This mechanism is also consistent with prior observations during maternal dehydration in sheep. ¹⁹⁻²¹ This reemphasizes the fact that the changes in plasma osmotic pressure are potentially much more powerful than vascular hydrostatic pressure changes because each 1 mOsm/kg change in osmolality can produce up to 19.7 mm Hg of osmotic pressure change at 39.5° C. Thus the late increase in maternal osmolality appears to have determined the net fetal fluid response to the Ringer's infusion. However, if this were the case, a transient in-

crease in fetal fluid status would have been expected after 1 to 2 hours of Ringer's infusion when the changes in maternal hydrostatic and osmotic pressure both favored fluid transfer to the fetus. In fact, there was a slight but not statistically significant increase in fetal urine flow at that time. This suggests that there may have been a transient increase in fetal blood volume causing the fetal diuresis.

Unlike the Ringer's infusion, the hypotonic infusion resulted in significant increases in fetal urine flow when maternal plasma osmolality was lowered by as little as 3% to 5%. However, the increase in fetal urine flow was delayed relative to the decrease in maternal plasma osmolality such that, for the first hour of the infusion, fetal urine flow did not change despite a significant

1514 Powers and Brace

drop in maternal plasma osmolality to 10 mOsm/kg below control. Thereafter, there was a gradual increase in fetal urine flow over the second hour of the infusion. This finding is consistent with prior studies in waterloaded adults22 where peak water diuresis was delayed for 90 to 120 min, the time required for clearance of arginine vasopressin from the extracellular space. The decrease in fetal plasma arginine vasopressin concentration in this study was similarly delayed, suggesting that the delayed rise in fetal urine flow was due to a delayed clearance of arginine vasopressin from the fetal circulation. Furthermore, the decrease in urine osmolality paralleled the decrease in fetal plasma arginine vasopressin. Thus the changes in fetal urine flow and osmolality are consistent with the observed changes in fetal plasma arginine vasopressin concentrations.

When the hypotonic experiments were separated into those where the animals began with a low urine flow during the control period versus those with an initial high flow, there was a significant difference in the response to a lowering of maternal osmolality. In animals where the fetus had an initial low urine flow, there was a significant increase in urine output with hypotonic infusion, whereas there was no increase in urine output in those animals with a high urine flow during the control period, in spite of similar decreases in maternal and fetal osmolality. This suggests that, when fetal urine flow is high and plasma arginine vasopressin concentration is low, arginine vasopressin does not affect the fetal kidney. Thus any further reduction in fetal arginine vasopressin level during hypoosmolality does not alter fetal urine flow or osmolality.

The alterations in fetal urine osmolality, electrolyte concentrations, and flow certainly suggest fluid moved into the fetus during the hypotonic infusion, and fluid was withdrawn from the fetus late during the Ringer's infusion. However, this could not be documented by a statistical change in fetal vascular pressures, blood volume, or amniotic fluid index. This apparent discrepancy can be explained by the fact that only about a 100 to 200 ml change in fetal fluid volume was expected during the 4-hour infusions. Futhermore, previous studies have found that little fluid was retained intravascularly in the fetus after short-term²⁸ or chronic¹⁸ intravascular infusions. Thus the lack of change in fetal blood volume is not inconsistent with the concept that fluid was transferred into the fetus during the hypotonic infusions and out of the fetus late during the Ringer's infusion when maternal plasma osmolality was elevated. This does not diminish the importance of maternal vascular or osmotic pressure changes in overall fetal fluid balance, because the volume of fluid which may have crossed the placenta would result in an enormous fluid flux over the course of gestation. Long-term studies will be necessary to document changes in parameters other than fetal urine flow.

In summary, our study failed to support the hypothesis that acute increases in maternal vascular pressures would promote fluid transer to the ovine fetus. Instead, the fetal fluid response to maternal volume loading appeared to be determined by the changes in maternal osmolality, with decreases in maternal osmolality producing an increase in fetal urine flow and vice versa. Over a period of days, these changes could potentially significantly alter fetal fluid balance.

The technical assistance of Eddie Kwan, Wendy Ewing, Kathy Aoyama, and Tammy Tetzke is greatly appreciated.

Oxytocin secretion and human parturition: Pulse frequency and duration increase during spontaneous labor in women

Anna-Riitta Fuchs, DSc,^a Roberto Romero, MD,^b David Keefe, MD,^b Manuel Parra, MD,^c Enrique Oyarzun, MD,^c and Ernesto Behnke, MD^c

New York, New York, New Haven, Connecticut, and Santiago, Chile

The secretory pattern of oxytocin was determined in blood samples taken at 1-minute intervals for 30 minutes from 32 parturient women. The samples were collected in a manner that minimized degradation by plasma oxytocinase, and a highly specific antibody was used for the radioimmunoassay. The results indicated that oxytocin is secreted in discrete pulses of short duration. The frequency of the pulses was significantly higher during spontaneous labor than before the onset of labor. The mean pulse frequencies per 30 minutes were 1.2 ± 0.54 before labor, 4.2 ± 0.45 during the first stage, and 6.7 ± 0.49 during the second and third stages of labor. The mean pulse durations in these three groups were 1.2 ± 0.20 , 1.9 ± 0.28 , and 2.0 ± 0.26 minutes, respectively. The amplitude of the pulses was variable with no significant differences between the groups, the majority being around $1.0~\mu\text{U/ml}$. The spontaneous pulses were of similar magnitude as those measured in 18 women after intravenous injections of 4 to 16 mU of oxytocin, which doses stimulated uterine contractions. We therefore conclude that the pulses of oxytocin observed at increasing frequency during spontaneous labor are of physiologic significance and provide evidence for the participation of oxytocin in the onset and maintenance of spontaneous labor. (AM J OBSTET GYNECOL 1991;165:1515-23.)

In spite of clear evidence for increased secretion of oxytocin during parturition in animals, changes in maternal oxytocin secretion rates during labor in women remain a matter of controversy. Both the absolute levels in peripheral circulation and the temporal variations in the course of labor vary widely in the published reports. Some authors found maternal oxytocin levels to remain unchanged throughout late pregnancy and labor, others found increasing levels in late pregnancy but decreasing levels during labor, and others observed a rise in the second stage only. In our laboratory we consistently found maternal levels to be

slightly but significantly raised over term—no labor values. Using a bioassay, Coch et al. found maternal levels in the "jugular" vein (obtained through a catheter pushed cranially into the subclavian vein) to be increased during labor with maximal levels in the second stage, whereas samples of peripheral plasma obtained at the same time showed no increase. Characteristic for all studies, whether performed by radioimmunoassay (RIA) or bioassay, is the great variability between individual values, even in patients not in labor. In fact, Chard and Gibbens reported their results in terms of the percentage of samples that showed values above the detection limit; they found that this percentage increased in the course of labor and concluded that their findings might indicate spurt release.

Dawood et al.⁶ reported widely fluctuating minuteto-minute variations in six pregnant women, three of whom were in labor. The authors interpreted these fluctuations as pulses, although they did not show pulse characteristics and may have represented the random variability of their assay.

The measurement of circulating oxytocin in pregnant women is difficult because of its slow plasma concentration, which in turn is a consequence of the extreme potency of oxytocin to stimulate the uterus at term. On the basis of oxytocin infusion studies, the effective concentrations at term are estimated to be in the range of 1 to 10 pmol/L. Another factor contributing to the difficulties is the presence of the enzyme oxytocinase (L-cystine-aminopeptidase) in high concentrations in pregnancy plasma of primates. This enzyme rapidly degrades the endogenous oxytocin present in the blood samples after they have been withdrawn, unless special precautions are taken. Moreover, the degradation products may share epitopes with the intact molecule and therefore may cross react with some of the antibodies used in the current RIAs. This may explain the differences in the absolute oxytocin levels reported in the literature.

If oxytocin were secreted in a pulsatile manner in women as it is in cows¹ and sheep,¹⁰ the measurement of oxytocin secretion rates is further complicated. The wide fluctuations in maternal plasma levels observed in most studies are compatible with a pulsatile pattern of release, but the sampling frequency has not been sufficient to demonstrate a pulsatile pattern in the previous studies nor were any of the studies subjected to rigorous analysis of the data to exclude random variations due to extraction and RIA procedures. The purpose of this study was to reexamine the secretory pattern of oxytocin in pregnant women before and during labor with a highly specific and sensitive antibody and a high sampling frequency, together with the application of precise criteria for pulse identification.

Material and methods

Subjects. Fifty pregnant women (38 to 42 weeks of gestation) without any serious medical or obstetric complications participated in this study, which was approved by the institutional ethics boards and human rights committees at both institutions concerned in the patient selection (Yale—New Haven Hospital and Hospital Sotero del Rio). All patients gave consent to have serial samples of blood taken during a 30-minute period. Uterine activity was monitored in all patients by means of external cardiotocography (Advanced Medical Technology, Humden, Conn.).

Sample collection. Samples (5 ml each) were collected with 1-minute intervals for 30 minutes from the following three groups of women (150 ml total volume from each woman): (1) women at term scheduled for elective cesarean section who had a closed cervix and were not in labor (n = 11), (2) women in the first stage of spontaneous labor with <6 cm cervical dilatation (range, 2.5 to 5.5 cm; mean \pm SD, 4.5 \pm 1.17 cm; n = 13), (3) women in the second stage of spontaneous labor with full dilatation of the cervix (n = 8). Five of the women of group 3 were delivered during the sampling period. Samples continued to be taken until the delivery of the placenta, and the sampling period in these patients therefore includes both the second and third stages. An additional fourth group of pregnant women at term was included (n = 18). They were not in labor and were given a bolus injection of oxytocin intravenously; the dose given was 2, 4, 8, or 16 mU. Most women had only one dose each; a few were given another dose 15 to 30 minutes after the first dose. Eight blood samples of 5 ml were collected in each instance (total, 40 ml) beginning immediately before and 30 seconds after, and 1, 2, 3, 4, 5, and 10 minutes after the intravenous injection.

The samples were collected from an indwelling heparin-lock catheter into precooled tubes containing an excess of ethylenediaminetetraacetic acid (0.37 mol/L) to inhibit the activity of oxytocinase. We did not add phenanthroline because in the dose recommended it caused hemolysis. The tubes were immediately put into an ice bath and kept on ice at all times. They were centrifuged at 4° C as soon as possible and plasma was immediately separated, acidified to pH 2 with hydrochloric acid (1N, 0.2 ml/ml plasma), and frozen until assayed. The low pH inhibits oxytocinase activity.

Oxytocin assay. Two milliliters plasma was used for each assay. The acidified plasma was diluted with an equal volume of 0.2N hydrochloric acid and passed through a column containing 500 mg heat-activated Florișil (Sigma, St. Louis). Oxytocin was eluted from the column with 90% acetone in water; the extracts were dried and then dissolved in 250 µl of assay buffer.

Standards in the range from 0.125 to 5 µU/ml were added to charcoal-treated pregnancy plasma and extracted in the same way as the unknowns with each assay to determine extraction recovery. The antibody used was a gift from Dr. Mariana Morris, Department of Physiology, Bowman Gray School of Medicine, Winston Salem. It is highly specific and sensitive and does not, in contrast to our old oxytocin antibody,12 cross react with the estrogen-induced peptide that was first described by Amico et al.13 The antibody has been validated for use in pregnant primates14 and pregnant women.15 Separation of bound and free ligand was by means of Pansorbin cells (Calbiochem, San Diego). During these studies the detection limit was 0.1 to 0.2 μU/ml (mean, 0.17 μU/ml) after correction for extraction recovery, which was $65.4\% \pm 8.7\%$ (mean \pm SD). The mean intraassay coefficient of variation was 11.3% and the interassay coefficient of variation was 15.7%. All samples from one patient were run in the same assay. The standards were from the National Bureau of Standards, London, which performs the standardization by bioassay and expresses the oxytocin concentrations in international units, approximately 1.68 µg peptide per 1 IU.

Plasma oxytocinase activity determinations. One sample from each patient was used for measuring Lcystine aminopeptidase activity. S-Benzyl-L-cysteine-βnitroanilide was used as a substrate.16 Before assay, the sample was neutralized to pH 7.4 and an excess of Ca++ (10 mmol/ml) was added to reactivate the enzyme. All chemicals were from Sigma.

Data analysis. The RIA results were calculated after logit-log transformation of the data with a computerized program (National Institutes of Health RIA logit),17 which also calculates the coefficient of variation at each level of standards and unknowns. Pulse analysis was performed according to the computerized method (Pulsar) of Merriam and Wachter. 18, 19 A calibration data set for the selection of cutoff criteria was created by analyzing three pools of pregnancy plasma in 30 duplicate samples each. One pool was charcoal treated, to represent baseline, one had 0.75 μ U/ml, and the third 1.5 μ U/ml added. The cutoff criteria selected were 3 × SD for single peaks and $2.5 \times SD$ for broader peaks. This minimized spurious peaks (0% in the baseline pool) and maximized the detection of peak levels in the other two pools. Mean peak pulse oxytocin level and mean overall oxytocin level were calculated for each patient (for nondetectable values the detection limit of the assay was used). The means for individual patients were used to calculate the means for each group; therefore n =number of patients. The values given are group means \pm SE, with n in parentheses. The pulse dura-

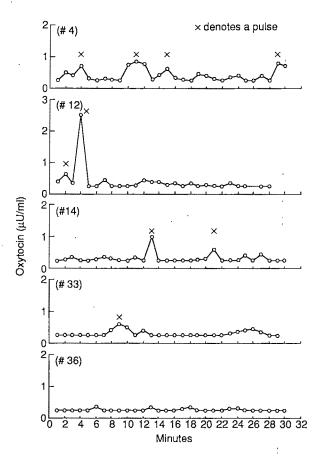

Fig. 1. Plasma oxytocin levels in five women in late pregnancy not in labor. Samples were collected at 1-minute intervals from indwelling catheter in right arm. Data plots in this and Figs. 2 and 3 were chosen to show the highest and lowest pulse frequencies and amplitudes in each group. Each identified pulse is denoted with cross. Six women of 11 in the no-labor group showed no pulses during study period.

tion was defined as the number of consecutive 1minute samples that the level was above the pulse limit.

Statistical analysis. One-way analysis of variance was used to compare the mean values for the three groups, followed by Dunnett's test. A value of p < 0.05 was considered significant; the Student t test was used when two groups were compared.

Results

The basal levels of oxytocin were below detection limit of the assay, 0.17 µU/ml, in all patients. In the 11 women not in labor (group 1), the percentage of samples below detection limit was 85%, it was 30% in group 2 (13 women in the first stage of labor), and it was 16% in group 3 (eight women in the second and third stages of labor). The mean pulse limit for single peaks was $0.45 \,\mu\text{U/ml}$ (baseline $\pm 3 \,\text{SD}$ at baseline), and all values exceeding this level were considered pulses. Discrete pulses of oxytocin were observed in all groups. They

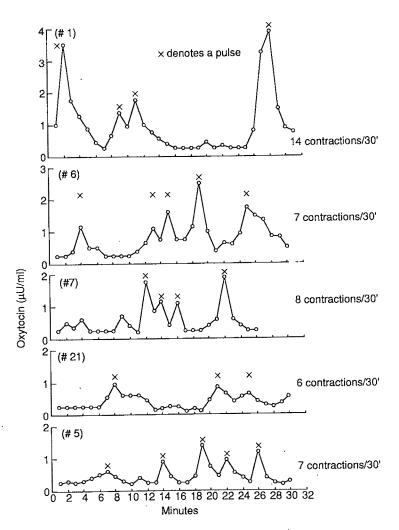

Fig. 2. Plasma oxytocin levels in five pregnant women during first stage of labor (cervix, 2 to 5 cm dilated). For details, see legend to Fig. 1. All women in this group had oxytocin pulses during study period.

occurred at irregular intervals and had variable amplitudes (peak levels). All were of short duration, 1 to 3 minutes. Thirty-minute plots of the data from several women in each group are shown in Figs. 1 through 3. The plots selected show the range of variability observed in each group, with the one showing the highest frequency and amplitude of pulses at the top and those showing the lowest pulse frequency and amplitude at the bottom of each figure (Figs. 1 through 3).

The frequency of oxytocin pulses was lowest in women not in labor (group 1), who had on the average 1.2 ± 0.54 pulses per 30 minutes; several of the women of this group (6 of 11) had no pulses during the study period. All women in labor, on the other hand, had oxytocin pulses; the mean frequency during the first stage of labor (group 2) was 4.2 ± 0.54 pulses per 30 minutes (range, 1 to 7 per 30 minutes), and during the second and third stages (group 3) the pulse frequency was 6.5 ± 0.49 pulses per 30 minutes (range, 4 to 8

per 30 minutes). The differences in pulse frequency were highly significant, p < 0.001 (Fig. 4).

The amplitude of the pulses (peak levels) ranged from 0.5μ to 8.2μ U/ml, but the majority were in the range of 0.5 to 1.5 µU/ml in all groups. The mean pulse amplitude in women not in labor (group 1), $0.91 \pm 0.20 \,\mu\text{U/ml}$ (n = 11), was lower than in women in labor, $1.10 \pm 0.10 \,\mu\text{U/ml}$ (n = 21) (groups 2 and 3 combined), but the difference was not significant. Women in the second and third stages of labor had the highest mean pulse amplitude, $1.40 \pm 0.35 \, \mu \text{U/ml}$ $(p < 0.05 \text{ vs group } 1, \alpha_1)$. The mean duration of the pulses was also increased in women in labor in comparison with those not in labor, 1.94 ± 0.21 versus 1.2 ± 0.14 minutes (groups 2 and 3 vs group 1, p < 0.01, α_2). As a result of the higher pulse frequency, amplitude, and duration the overall mean plasma levels of oxytocin were significantly higher in women in labor than in women not in labor (Table I).

Effect of exogenous oxytocin. Injection of oxytocin as an intravenous bolus resulted in a detectable rise in plasma oxytocin levels in all women except some of those receiving the lowest dose, 2 mU. Peak levels were usually observed at 30 seconds, in a few instances at 1 minute after the injection. The rise was dose dependent (Fig. 5). A significant rise was detected in two of six patients receiving the 2 mU dose and in all receiving the other doses, 4, 8, and 16 mU. Peak levels were similar to those observed during spontaneous pulses; the majority of spontaneous pulses resembled those produced by 4 and 8 mU injected intravenously.

The injections of oxytocin caused uterine contractions in the majority of women; in two of five receiving 2 mU; four of five receiving 4 mU, five of six receiving 8 mU, and one of two receiving 16 mU. A series of contractions leading to the onset of labor occurred in one woman after the injection of 8 mU of oxytocin. On the average, the number of contractions in the first 10 minutes after the injection was correlated with the mean peak plasma level in each group (Fig. 6), but the correlation in individual women between the peak plasma oxytocin level and the number of contractions recorded by external tocography was not significant.

Plasma oxytocinase. Plasma oxytocinase activity was present in all women (range, 25 to 105 U/L). The women in labor had higher oxytocinase activity than those not in labor, but the extraction recovery of oxytocin, which was measured in one sample from each individual patient, was not correlated with plasma oxytocinase activity, indicating that the rapid cooling and addition of ethylenediaminetetraacetic acid were effective in blocking the enzyme activity during sample preparation. In samples taken during infusions of 10 mU oxytocin per minute we found the levels to be similar (3 to 4 µU/ml) as those reported by Thornton et al.11 who used a combination of phenanthroline and ethylenediaminetetraacetic acid in concentrations that they claim to be 100% effective in preventing oxytocinase activity. Some inactivation of plasma oxytocin may of course have occurred while the blood was being drawn and before it became thoroughly mixed with the ethylenediaminetetraacetic acid in the tube and was cooled. Our data therefore may underestimate the true values somewhat.

Comment

Our results unequivocally demonstrate that the secretion of oxytocin is significantly increased in spontaneous labor in comparison with women at term but not in labor. The secretion occurs in short pulses, and the frequency of these pulses is significantly increased during labor. There is no absolutely right method to use in the analysis of episodic hormone secretion. We have chosen the method of Merriam and Wachter¹⁸. ¹⁹

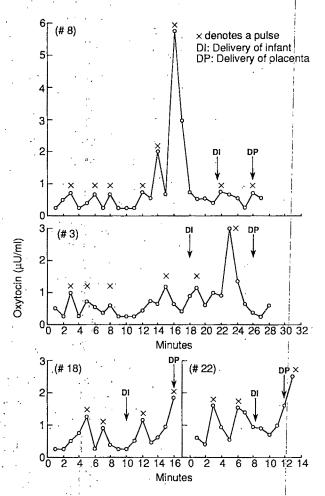

Fig. 3. Plasma oxytocin levels in three pregnant women during second and third stages of labor. *DI*, Delivery of infant; *DP*, delivery of placenta.

because it takes into account the assay variability at each point and rescales all identified peaks in terms of this unit, an important consideration that the levels are so low as plasma oxytocin. The cutoff values are based on the width of each peak, and the algorithm selects both narrow high peaks and broader peaks that may be lower. The program does not depend on pattern recognition, nor does it require a pattern in the timing of the peaks that may be inherently irregular, as is the case with oxytocin secretion. The choice of cutoff criteria is based on empiric considerations. Increasing the cutoff criteria for our data would have decreased the number of identified pulses but would not have changed the conclusion, namely, that the frequency of pulses was increased during labor in comparison with no-labor válues.

Of particular interest is the finding that oxytocin secretion is significantly increased in early labor, in our experimental subjects at cervical dilatations of 2 to 5 cm. We did not observe a marked and prolonged increase in plasma oxytocin during the third stage of

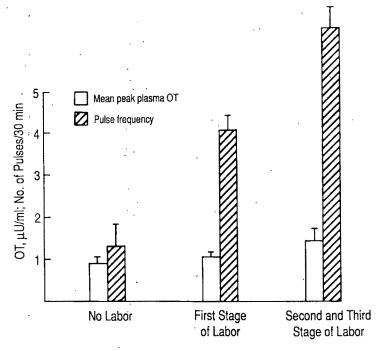

Fig. 4. Mean oxytocin pulse frequency and amplitude determined in women at term, not in labor (n = 11), during first stage of labor (n = 13), and combined second and third stages of labor (n = 8). Oxytocin concentrations were measured by RIA in samples collected at 1-minute intervals for 30 minutes in each group; values greater than baseline \pm 3 SD were considered a pulse. Means of all pulses in individual patient were calculated. Values given represent mean of these means \pm SE; n = 1 number of patients in each group.

Table I. Oxytocin secretion in pregnant and parturient women at term

Group	n	Pulse frequency (No./30 min)	Pulse duration (min)	Pulse amplitude (µU/ml)	Mean oxytocin over 30 min (μU/ml)	Cervical dilatation (cm)
Group 1. No labor	11	1.3 ± 0.54	1.2 ± 0.20	0.91 ± 0.20	0.26 ± 0.041	Closed
Group 2. First stage	13	$4.2 \pm 0.45*$	$1.9 \pm 0.28*$	0.92 ± 0.12	$0.42 \pm 0.04*$	4.5 ± 1.2
Group 3. Second and third stage	8	$6.5 \pm 0.49 \dagger$	2.0 ± 0.26*	1.4 ± 0.35	$0.65 \pm 0.12*$	10

Values are mean ± SE of means for individual patients; n, number of patients.

labor as seen by Thornton et al.11 in about 40% of patients.

The pulse amplitude during labor, although variable, was generally low, on the average, $1.1~\mu\text{U/ml}$, and not significantly greater than in women not in labor. Similar pulses were produced by injections of 4 to 16 mU of oxytocin. Since injections of these doses were effective in eliciting uterine contractions in women at term, the observed levels are of physiologic significance and are adequate for the activation of the myometrium at term and at the onset of spontaneous labor in particular, because of the prelabor rise in uterine oxytocin sensitivity to maximum values. ^{20, 21} Pulsatile oxytocin was found to be more effective per unit oxytocin than

continuous infusion in inducing uterine contractions and delivery in pregnant rats.²² Lower total doses were required with pulsed oxytocin than continuously infused oxytocin to induce labor in pregnant women.^{23, 24} In spite of higher intermittent pulse doses per minute than with the continuous infusion rates (mean maximum, 50 ± 4 mU/min every 10 minutes vs 20.2 ± 2.3 mU/min²³ and mean maximum, 41.6 ± 6 mU/min every 8 minutes vs 9.2 ± 1.8 mU/min²⁴), the total dose required was only 30% to 50% of the dose administered by continuous infusion. The pulsatile secretion pattern therefore provides more effective myometrial stimulation than does a constant tonic secretion.

^{*}Significant differences from values in women not in labor.

[†]Significant differences between values in first stage and second stage of labor.

Values are mean; bars indicate SE; n is in parentheses. Dotted line, Mean pulse limit (cutoff criterion) for spontaneous pulses.

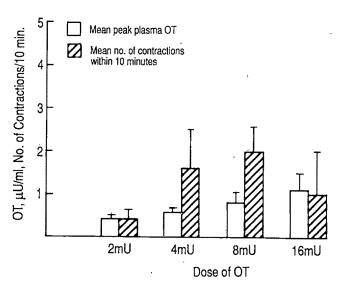

Fig. 6. Comparison of peak plasma oxytocin levels observed after intravenous injection of 2, 4, 8, and 16 mU oxytocin and number of contractions recorded by external cardiotocometer after each injection. Values are mean \pm SE; for n, see Fig. 2.

The fact that not every woman receiving an injection of oxytocin responded with contractions, although a given dose produced similar oxytocin levels in all, is in keeping with clinical observations of individual variations in uterine responsiveness to oxytocin near term. It is also in harmony with our previous findings regarding myometrial oxytocin receptor concentrations near term and during labor.20 Considerable individual 1522 Fuchs et al.

November 1991
Am I Obstet Gynecol

variations in oxytocin receptor concentrations were present at 36 to 40 weeks of gestation before the onset of labor, but at the early stages of labor all women had significantly higher receptor concentrations than before the onset of labor. A good correlation was found between the rise in myometrial oxytocin receptor concentrations in early labor and the rise in uterine responsiveness to oxytocin in the last days of gestation.²¹

The factors responsible for the increased secretion of oxytocin in the early stages of labor are not known. Oxytocin is usually, but not always, secreted in response to neural stimuli. The uterine corpus and fundus are virtually depleted of neurotransmitters during pregnancy, and they are not replenished until sometime after delivery.25 Uterine innervation is therefore not likely to participate in the release of oxytocin at term. However, the innervation of the cervical region, which has a rich supply of both adrenergic and vasoactive intestinal polypeptidergic nerves, is retained unaltered during pregnancy25 and could play a role in the release mechanism of oxytocin at the onset of labor. In support of this notion is our finding that many women with cervical incompetence, particularly those who subsequently had preterm deliveries, have increased oxytocin levels in midpregnancy.15 The actual stimulus could be provided by pressure exerted by the descending fetus on the internal os from above or by the increasing tension to which the cervical region is subjected by the increasingly distended upper segment of the uterus. A reflex release of oxytocin in response to the distension of the cervix and the uterine body was postulated by Ferguson²⁶ in 1941 but its existence has so far not been convincingly demonstrated except in the ewe, goat, and rat.27-29 Fish et al.30 tried to cause oxytocin release by experimentally stretching the cervix in women in early labor with a balloon inserted inside the uterus in front of the amniotic sac. The balloon was inflated with 350 ml water, and strong traction was applied that dilated the cervix from 3 to 6 cm but did not cause milk ejection responses, as measured by simultaneous recording of intramammary pressure. Moreover, animal studies indicated that stimulation of organs in the deep pelvic cavity27 or vagina30 was more effective in eliciting oxytocin release than the manipulation and stretching of the cervix, and it is therefore possible that afferent pelvic nerves in various organs of the pelvis rather than in the cervix could be responsible for the release of oxytocin at the onset of labor in women. Vaginal distention may have elicited some of the increases in the late second stage and third stage reported by various authors.

In conclusion, we have shown that in pregnant women at term, oxytocin is secreted in short pulses of variable amplitude. During labor the secretion increases significantly. The increase involves mainly a rise in pulse frequency and to a lesser degree in pulse amplitude and duration. The spontaneous pulses are similar in magnitude as those produced by doses of oxytocin injected intravenously (4 to 16 mU) that are capable of eliciting uterine contractions in women at term. The spontaneous pulses of oxytocin therefore are likely to play a major role in uterine activation during spontaneous labor.

We thank Jaana Rehnström, MD, New York, and her patients for providing us with the pool of pregnancy plasma that made this study possible. We also acknowledge the excellent technical assistance of Dulce Navarro, BS, and the gift of the oxytocin antibody from Dr. Mariana Morris, PhD, Departments of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston Salem.

Dose-dependent effects of angiotensin II on the ovine fetal cardiovascular system

Oliver W. Jones III, MD, Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD San Diego, California

The purpose of this experiment was to establish dose-response relationships for the effects of angiotensin II on arterial pressure, venous pressure, heart rate, and blood volume in the ovine fetus. Chronically catheterized fetal sheep at 132 \pm 1 (SE) days' gestational age were infused with angiotensin II at 4.8 \pm 1.1 (n = 7), 27.7 \pm 4.6 (n = 7), 102.2 \pm 16.7 (n = 6), or 239.0 \pm 30.9 (n = 4) ng/min/kg fetal body weight for 30 minutes. Fetal arterial pressure increased at the three highest doses. Fetal venous pressure, heart rate, and blood volume responded only at 102.2 and 239.0 ng/min/kg. Åt 239.0 ng/min/kg, arterial pressure increased by 17.7 \pm 1.6 mm Hg (p < 0.00001), venous pressure increased by 1.5 \pm 0.3 mm Hg (p < 0.0005), blood volume decreased by 7.8 \pm 2.2% (p < 0.0001), and heart rate initially decreased by 14 \pm 4 beats/min, followed by an increase of 52 \pm 17 beats/min from control (p < 0.0005) at the end of angiotensin II infusion. Thus this study shows that angiotensin II affected multiple fetal cardiovascular variables in a dose-dependent manner, suggesting that it is an important regulatory hormone for the entire fetal cardiovascular system. (AM J OBSTET GYNECOL 1991;165:1524-33.)

Key words: Ovine fetus, arterial pressure, venous pressure, heart rate, blood volume, angiotensin II

Angiotensin II is a potent vasoconstrictive hormone in the fetus and the adult. The early work of Broughton-Pipkin et al.1 and others2-4 has shown that an active renin-angiotensin system is present in the ovine fetus as early as midgestation. Its major function appears to be maintenance of fetal arterial pressure under conditions of fetal stress, such as acute hemorrhage or hypoxia.1-3 Several investigators have examined the effects of exogenous angiotensin II in the ovine fetus. Previous studies have demonstrated a pressor effect on arterial pressure in the fetus.5-11 Clark et al.9 and Yoshimura et al.10, 11 reported a dose-response relationship for brief infusions (5 minutes) in the fetus. The doseresponse relationship for longer infusions has not been reported. In addition, the effect of angiotensin II on fetal heart rate (FHR) is unclear in that Iwamoto and Rudolph⁷ and Robillard et al.8 reported an increase in FHR after administration of angiotensin II to the fetus. Clark et al.9 and Yoshimura et al.10, 11 reported a decrease in FHR. Ismay et al.6 found that the heart rate response was dependent on fetal arterial pressure. Furthermore, the effects of angiotensin II on fetal venous pressure or blood volume have not been previously investigated. Because of these unknowns and contradictory effects of angiotensin II on FHR, we chose to examine in more detail its effects on the cardiovascular function of the fetus. We were particularly interested in determining whether it can modulate parameters of the fetal cardiovascular system in addition to arterial pressure. Thus our study was conducted to establish dose-response relationships in the near-term fetal sheep for the effects of angiotensin II on arterial pressure, venous pressure, heart rate, and blood volume.

Methods

Time-dated pregnant sheep were used for this study. The surgical preparation has been described in detail elsewhere.12 In brief, pregnant ewes with singleton fetuses at 126 ± 1 days' gestation were anesthetized with intravenous thiamylal sodium, intubated, and maintained on gas inhalation anesthesia (halothane, 1% to 2% in oxygen). A midline incision was made in the maternal abdomen, exposing the uterus. An incision was made in the uterus, and the hindlimbs of the fetus were exteriorized. Catheters were placed in a pedal artery and saphenous vein of each leg. Two additional catheters were attached to the fetal skin to measure amniotic fluid pressure. The catheters were exteriorized to a pouch sewn on the maternal flank. Postoperatively, the mother received penicillin G (600,000 U) and dihydrostreptomycin sulfate (750 mg) intramuscularly for 5 days, and ticarcillin disodium (500 mg) with clavulanate potassium (16 mg) was injected daily into the amniotic cavity for 5 days. Experimentation

began on postoperative day five. This protocol was approved by our institution's animal subjects committee.

The experimental protocol consisted of a 30-minute control period and a 30-minute infusion of angiotensin II, followed by a 30-minute recovery period. Fetal arterial pressure, venous pressure, amniotic fluid pressure, and heart rate were continuously recorded on a polygraph recorder (Gould), and 30-second averages were stored on an on-line computer (Hewlett-Packard) as previously described.13 The vascular pressures were referenced to the standard zero pressure reference for the fetus by continuously subtracting amniotic fluid pressure with the on-line computer. At the lowest infusion rate the venous pressure could not be recorded in one fetus.

Before experimentation the pressure transducers were checked for zero drift over several hours and only transducers with minimal drift were used. Zero baseline pressure values were determined at the beginning of the experiment. On completion of each experiment baseline pressure correction was made for any drift that might have occurred during the course of experimentation, assuming that drift was linear with time. Typically the drift was small (<1 mm Hg) or nonexistent.

Angiotensin II diluted in isotonic saline solution was infused intravenously into the fetus at rates of 10 (n = 5), 30 (n = 4), 100 (n = 5), 300 (n = 5), or 1000 (n = 5) ng/min at a flow rate of 0.39 ml/min. The infusion catheter (volume equaled 1.25 ml) was primed with infusate (0.8 ml) 30 seconds before the angiotensin II infusion was started. We have previously shown that vehicle infusion does not alter any of the monitored variables.14 One to three experiments were performed on each animal with 48 hours between experiments. Infusion rates were randomly assigned, and no animal received the same infusion rate more than once. A total of 24 experiments were conducted in 15 animals.

Samples of 3 ml of fetal arterial blood were obtained every 15 minutes, starting 10 minutes after the beginning of the protocol. This was replaced immediately with an equal volume of heparinized maternal blood obtained before starting the experiment. The fetal blood was used for the measurement of pH, Pco2, and Po₂ (Instrument Laboratory System 1302 pH/blood gas analyzer at 39.5° C), hematocrit in triplicate,15 osmolality (freezing point depression with an Advanced Digimatic osmometer model 3D2), plasma protein concentration (American Optical, TS meter), and Na+, K+, and Cl⁻ ion concentrations (Nova 5+5 electrolyte analyzer). The change in fetal blood volume as a percent of control was calculated as the mean control hematocrit during the 30-minute preinfusion period divided by the hematocrit of each sample, as previously described.15

Angiotensin II concentration in the infusate was

measured by a double-antibody radioimmunoassay as described previously16 with the following modification. The antiserum used for the assay was purchased from Peninsula Laboratory and was specific for human angiotensin II. The sensitivity of the assay was 0.3 pg, and the intraassay and interassay coefficients of variation were 4.0% and 3.4%, respectively. A 2 ml portion of each fetal blood sample was reserved for determination of angiotensin II concentration. However, our tests showed that the peptidase inhibitor (aprotinin) used in preserving the sample inadequately inhibited the degradation of angiotensin II. Therefore the results of the plasma angiotensin II assays were not accurate and could not be used. The protease inhibitor that we used differed from that used by Robillard et al.8 and Naden et al.,17 who used o-phenanthroline as the inhibitor in their plasma samples collected for angiotensin II measurements.

On completion of the experiment the animals were killed with an overdose of pentobarbital sodium solution. The fetuses were weighed after towel drying. Fetal weight on the day of experimentation was estimated, and a 3% increase in fetal body weight per day was assumed for fetuses not weighed on the day of experimentation.18 The weight-normalized infusion rates were determined from the measured infusate concentrations, and the fetal body weights were either obtained at autopsy or calculated as described above.

Data analysis. The infusion rates were divided into four groups on the basis of weight-normalized infusate concentrations measured by the assay: 4.8 ± 1.1 , 27.7 ± 4.6 , 102.2 ± 16.7 , or 239.0 ± 30.9 ng/min/kg fetal body weight. These groupings were selected to eliminate overlap of the infusion rates among the four

Data are expressed as the mean \pm SE. To determine whether changes with time in a variable were statistically significant, a two-factor analysis of variance for repeated measures was used, with animal and time being the two factors. Bivariate and polynomial regres-

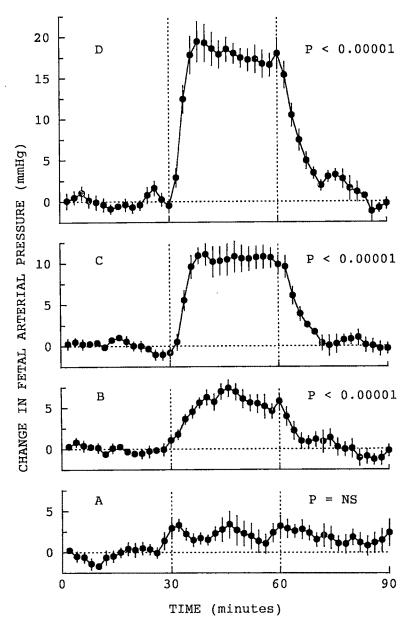

Fig. 1. Changes (mean \pm SE) in fetal arterial pressure during infusion of angiotensin II from 30 to 60 minutes. Data are expressed as change from control during 0 to 30 minutes. Infusion rates were 4.8 \pm 1.1 (A, n=7), 27.7 \pm 4.6 (B, n=7), 102.2 \pm 16.7 (C, n=6), and 239.0 \pm 30.9 ng/min/kg (D, n=4).

sion analysis was used to determine the relationship between infusion rate and response. Multivariate regression analysis was used to determine the relationships among several variables simultaneously. Results were considered statistically significant if $p \le 0.05$.

Results

Mean values for fetal arterial pressure, venous pressure, heart rate, arterial pH and blood gases, hematocrit, plasma protein, osmolality, Na^+ , K^+ , and Cl^- during the control period are shown in Table I. On the day of experimentation (n=24) the mean gestational

age of the fetuses was 132 ± 1 (SE) days. Mean fetal weight at the time of experimentation was 3.02 ± 0.17 kg.

Fetal arterial pressure increased significantly from baseline values during infusion of angiotensin II at all infusion rates except the lowest (p < 0.0001, Fig. 1). The rise in arterial pressure began quickly with the onset of infusion and reached a peak value within 4 minutes. The greatest increase in arterial pressure was 17.7 ± 1.6 mm Hg (p < 0.001); this occurred at the highest infusion rate. A decline in arterial pressure was observed within 2 minutes after the infusion was

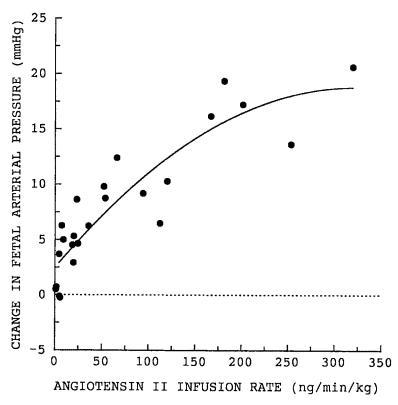

Fig. 2. Second-order polynomial regression plot of change in fetal arterial pressure averaged over last 20 minutes of angiotensin II infusion for each experiment (total of 24) versus infusion rate of angiotensin II (r = 0.90, p < 0.00001).

stopped. Polynomial regression analysis showed a significant correlation between the fetal arterial pressure response and infusion rate during the last 20 minutes of angiotensin II infusion (r = 0.90, p < 0.00001, Fig. 2).

Compared with the arterial pressure changes, the fetal venous pressure response to angiotensin II was less dramatic, with a significant increase occurring only at infusion rates of 102.2 ± 16.7 and 239.0 ± 30.9 ng/min/kg (p < 0.005, Fig. 3). At the lowest infusion rate there was an increase in venous pressure before the onset of the angiotensin II infusion. On review of the individual polygraph tracings, there was increased uterine activity and fetal movement occurring at this time, which probably accounts for this elevation in pressure. At $239.0 \pm 30.9 \text{ ng/min/kg}$, the peak increase in venous pressure was 1.5 ± 0.3 mm Hg. Similar to the arterial pressure response, the maximal increase in venous pressure occurred within 4 minutes of the onset of the infusion. With termination of infusion, venous pressure declined toward baseline within 1 to 2 minutes. Venous pressure declined below baseline during the recovery period at the two highest infusion rates, with a maximal decrease of 2.2 ± 0.7 mm Hg (p <0.05) at 239.0 \pm 30.9 ng/min/kg. At the highest infusion rate fetal venous pressure returned to baseline by the end of the recovery period. Linear regression analysis showed a significant relationship between the mean elevation in venous pressure during the last 20 minutes of the infusion and the infusion rate (r = 0.47, p < 0.05, Fig. 4). Analysis with polynomial regression did not produce a better-fitting regression line.

With the onset of angiotensin II infusion at 102.2 ± 16.7 and 239.0 ± 30.9 ng/min/kg, FHR decreased immediately. At an infusion rate of 102.2 ± 16.7 ng/min/kg, the FHR returned to baseline by the end of the infusion (Fig. 5). Heart rate then increased by 31 ± 12 beats/min during the recovery period (p < 0.0001, Fig. 5). At the highest infusion rate, the FHR initially decreased by 14 ± 4 beats/min after the onset of infusion. Heart rate subsequently increased gradually over the infusion period. During the recovery period, heart rate reached its maximum of 58 ± 19 beats/min above control (p < 0.0005, Fig. 5). Thereafter, FHR gradually fell toward baseline.

Blood volume decreased significantly during the highest two infusion rates. The maximal decrease was $7.8 \pm 2.2\%$ after 25 minutes of angiotensin II infusion at a rate of 230.0 \pm 30.9 ng/min/kg (p < 0.0005). Linear regression analysis showed a strong relationship between the infusion rate and the change in blood volume at the end of the infusion (r = -0.83,

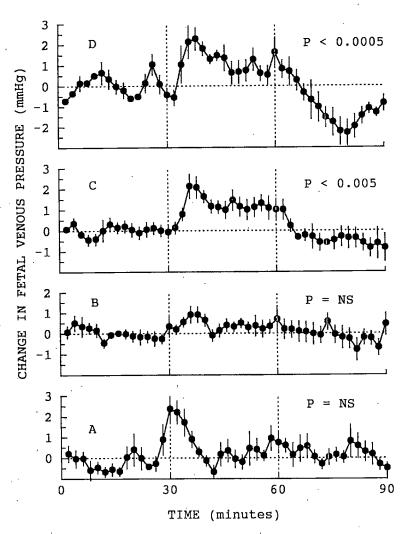

Fig. 3. Changes (mean ± SE) in fetal venous pressure during infusion of angiotensin II from 30 to 60 minutes. Infusion rates were 4.8 ± 1.1 (A, n = 6), 27.7 ± 4.6 (B, n = 7), 101.2 ± 16.7 (C, n = 6), and $239.0 \pm 30.9 \text{ ng/min/kg}$ (D, n = 4).

p < 0.00001, Fig. 6). In addition, a significant correlation existed between the change in fetal blood volume and arterial pressure responses during the last 20 minutes of the infusion (r = -0.86, p < 0.0001, Fig. 7). Similarly, a significant correlation was noted between the change in blood volume and the change in venous pressure at this time (r = -0.49, p < 0.05). However, with multivariate analysis the changes in fetal blood volume were statistically related to arterial pressure (p < 0.00001) but not to venous pressure. Blood volume remained reduced during the recovery period.

Plasma protein concentration increased significantly during the highest angiotensin II infusion rate, with the peak change being 0.27 ± 0.03 gm/dl (p < 0.05) after 25 minutes of infusion. There was no significant change in plasma protein concentration during the lowest or intermediate infusion rates.

Changes in fetal Pco2 and Po2 during or after an-

giotensin II infusion were nonsignificant, except for an increase in arterial Po₂ of 3.3 ± 0.9 mm Hg (p < 0.01) during the recovery period at the highest infusion rate. Fetal arterial pH decreased significantly during the recovery period after 27.7 ± 4.6 and 102.2 ± 16.7 ng/min/kg (p < 0.01). At 239.0 ± 30.9 ng/min/kg, the decrease began during the infusion and persisted into the recovery period (p < 0.001). The maximal observed decrease was 0.02 ± 0.01 pH units.

Plasma osmolality, Na+, Cl-, and K+ did not show significant changes during any infusion rate.

Comment

The purpose of this study was to explore dose-response relationships for the effects of angiotensin II on fetal arterial pressure, venous pressure, heart rate, and blood volume. To do this, we infused angiotensin II at mean rates of 4.8 \pm 1.1, 27.7 \pm 4.6, 101.2 \pm

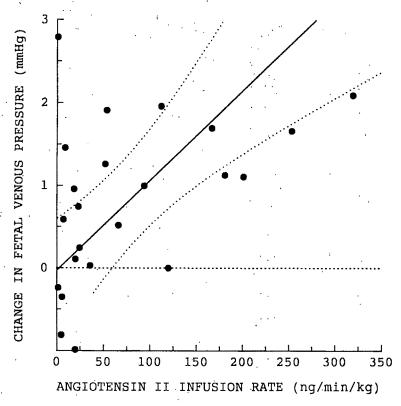

Fig. 4. Linear regression plot of change in fetal venous pressure averaged over last 20 minutes of angiotensin II infusion for each experiment (24 total) versus infusion rate of angiotensin II (r = 0.47, p < 0.05). Dashed lines, 95% Confidence interval about mean.

16.7, and 239.0 \pm 30.9 ng/min/kg of fetal weight for 30 minutes. Although fetal plasma concentrations were not available from this study, the plasma concentrations achieved during the infusions can be estimated from the work of other investigators. Specifically, Robillard et al.8 reported a fetal plasma clearance of infused angiotensin II of 170 ml/min/kg. From this it can be calculated that each nanogram per minute per kilogram infused would increase fetal plasma angiotensin II concentration by 5.9 pg/ml. Thus our four infusion rates would increase plasma concentration by approximately 28, 163, 603, and 1410 pg/ml, respectively. As most previous studies reported a basal fetal plasma concentration of 40 to 80 pg/ml with increments of several hundred picograms per milliliter under stress conditions.3.19 our infusions cover the physiologic range of fetal plasma angiotensin II concentrations.

The increase in arterial pressure that occurred during angiotensin II infusion appears to be a prompt and direct effect of angiotensin II, which, at the highest infusion rate, caused a 42% increase above control. Arterial pressure appeared to reach a steady state that persisted throughout the infusion period. With termination of the infusion, fetal arterial pressure rapidly returned to baseline values. Therefore, the arterial pressure response to angiotensin II appeared to be sus-

tained as long as circulating levels were elevated, but was teminated immediately as angiotensin II was cleared. This rapidity of onset of activity and subsequent clearance is consistent with the suggestion that angiotensin II is important in the initial response of the fetus to hypotension.^{1, 3, 19, 20}

In our experiments a maximal fetal arterial pressure response of approximately 21 mm Hg occurred at an infusion rate of 325 ng/min/kg (fig. 2). Other investigators infusing angiotensin II as a bolus21 or as a short (5 to 8 minutes) infusion9-11, 22 observed a similar increase in fetal arterial pressure at infusion rates comparable with those used in the current study. In addition, they also observed greater increases at higher infusion rates. Collectively, these studies suggest that the pressor effect of angiotensin II is dose dependent and increases linearly with increasing doses of angiotensin II. Thus findings with respect to fetal arterial pressure in the present experiment are consistent with the work of previous investigators. In addition, the responses are extended over a broader dose-response range for infusions lasting >5 minutes.

The observation of changes in central venous pressure of the fetus during angiotensin II infusion provides new information. The measured increases were subtle but significant. At the highest infusion rate, a

Fig. 5. Changes (mean \pm SE) in FHR during infusion of angiotensin II from 30 to 60 minutes. Infusion rates were 4.8 \pm 1.1 (A, n=7), 27.7 \pm 4.6 (B, n=7), 101.2 \pm 16.7 (C, n=6), and 239.0 \pm 30.9 ng/min/kg (D, n=4).

 1.5 ± 0.3 mm Hg increase in venous pressure was observed. This increase may indicate that the elevated arterial pressures were transmitted across the capillary bed or might indicate a direct effect of angiotensin II on venous resistance or capacitance vessels. This, coupled with the observation that the largest decrease in blood volume occurred simultaneously with the greatest increase in venous pressure, suggests that a venous constriction had occurred. The drop in venous pres-

sure during the recovery period after the highest infusion rate also appears to imply a decrease in vasoconstriction with termination of the angiotensin II infusion, because intravascular volume was decreased at that time.

The observation that fetal blood volume decreased in response to angiotensin II has not been previously reported. Blood volume most likely decreased as a result of increased capillary pressure and a shift of in-

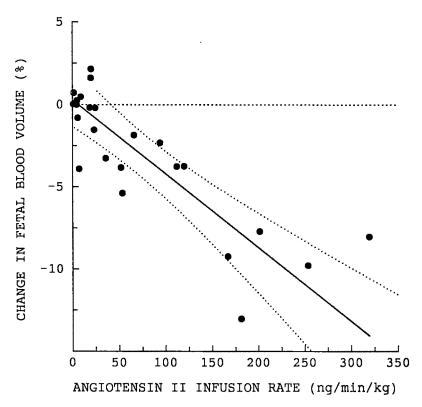

Fig. 6. Linear regression plot of change in fetal blood volume after 25 minutes of angiotensin II infusion versus infusion rate (r = -0.83, p < 0.0001). Dashed lines, 95% Confidence interval about mean.

travascular fluid into the interstitium. Fetal capillaries have a high permeability, and a significant increase in hydrostatic pressure would drive fluid across the capillary membrane.23 This is also consistent with the observed increases in plasma protein concentration. Blood volume remained reduced during the recovery period. This shows that return of the displaced fluid to the intravascular space was a gradual process.

In our study the FHR response to angiotensin II was biphasic in that there was an initial drop in heart rate, as much as 14 ± 4 beats/min at the highest infusion rate, followed by an increase within a few minutes. The initial decrease was probably baroreceptor mediated. The rise appears to be a direct effect of angiotensin II on the fetal heart, overriding the baroreceptor reflex. Because of the relative vascular hypertension, tachycardia cannot be attributed to the observed decrease in intravascular volume. In fact, both Iwamoto and Rudolph³ and Robillard et al. 19 showed in ovine fetuses that a decrease in fetal blood volume of as much as 20% did not produce a significant increase in FHR. In the current experiment, the persistent elevation in FHR observed after angiotensin II infusion may be secondary to the enhanced release or reduced reuptake of another cardiac chronotropic hormone, such as norepinephrine. This was suggested by our previous work¹⁴ in which the infusion of exogenous norepinephrine produced changes in FHR that were nearly identical to those observed in our study.

The observed changes in pH were slight, with the maximal change being only 0.02 pH units. Iwamoto and Rudolph⁷ and Robillard et al.⁸ reported no change in fetal pH, Pco2, or Po2 after angiotensin II infusion as high as 280 ng/min/kg. However, Yoshimura et al.¹⁰ reported a decrease in pH of 0.13 pH units and Po2 of 3.9 mm Hg with an increase in Pco₂ of 8.9 mm Hg after 5 to 7 minutes of angiotensin II at 5.73 µg/min. The effects of angiotensin II on umbilical vascular resistance and blood flow have been well documented. 9, 10, 22, 24 Angiotensin II increases umbilical vascular resistance and decreases flow. This alteration in umbilicoplacental flow may account for the slight changes in fetal pH observed in this study.

Our study suggests that differences in experimental design may be the cause for the differences in the FHR responses to angiotensin II reported by various investigators. Ismay et al.6 and Scroop et al.21 administered angiotensin II as a bolus to produce acute hypertension. The immediate baroreceptor response most likely produced a decrease in FHR. Such a finding was also seen by Clark et al.9 and Yoshimura et al.10,11 after a 5- to 7minute infusion of angiotensin II. However, bradycardia was only a transient response. Iwamoto and Rudolph⁷ and Robillard et al., with infusion rates sim-

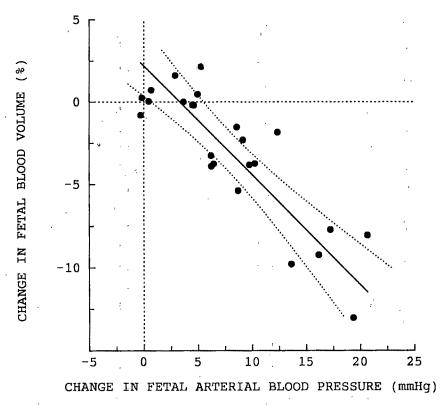

Fig. 7. Linear regression plot of change in fetal blood volume after 25 minutes of angiotensin II infusion versus change in fetal arterial blood pressure (r = -0.86, p < 0.0001). Dashed lines, 95% Confidence interval about mean.

ilar to the present study, reported an increase in FHR when a steady-state angiotensin II response was achieved. The short-term chronotropic cardiac response to angiotensin II appears to be an acute decrease in FHR mediated by the baroreceptor reflex, followed by an increase in FHR, possibly due to direct effects of angiotensin II on the fetal heart or increased release of endogenous cardiac catecholamines.

The response of the fetal cardiovascular system to angiotensin II bears similarities to that of norepinephrine. Norepinephrine infusion according to the same protocol as used in this study increased fetal arterial pressure in a dose-dependent manner.14 The venous pressure response to norepinephrine infusion was similar to the venous pressure response after angiotensin II. Like the angiotensin II infusion, the venous pressure effects were seen only at the higher norepinephrine infusion rates. The FHR responses to norepinephrine were nearly identical to those with angiotensin II, and a similar decrease in blood volume was observed. The similarities in the fetal cardiovascular responses between angiotensin II and norepinephrine may suggest that some of the cardiac effects of angiotensin II may be mediated by norepinephrine. Further investigation of any altered effect of angiotensin II in

the autonomically blocked fetus may support this possibility.

In summary, this study extends previous observations on the fetal arterial pressure responses to angiotensin II and provides new information about its effects on fetal venous pressure, heart rate, and blood volume. Collectively, these observations suggest that angiotensin II may be an important regulatory hormone for the entire fetal cardiovascular system.

In vivo and in vitro effects of magnesium sulfate in the cerebrovascular bed of the goat

Alfredo J. Perales, MD, ^{a, d} Germán Torregrosa, PhD, ^b Juan B. Salom, PhD, ^b Francisco J. Miranda, MD, ^b José A. Alabadí, BSc, ^b Javier Monleón, MD, ^{a, d} and Enrique Alborch, MD^{b, c}

Valencia, Spain

The effects of magnesium sulfate in the cerebrovascular bed were studied both in vivo, by measuring cerebral blood flow in conscious nonpregnant goats, and in vitro, by recording isometric tension in isolated goat middle cerebral arteries. Injections of increasing doses (10 to 300 mg) of magnesium sulfate directly into the cerebral circulation elicited transient and dose-dependent increases in cerebral blood flow and decreases in cerebral vascular resistance. Similar results were obtained when increasing doses (0.3 to 3 gm/15 min) of magnesium sulfate were infused intravenously, although the vasodilatations reached a stable plateau that remained when the infusions finished. Cumulative addition of magnesium sulfate (10^{-5} to 3×10^{-2} mol/L) did not change the isometric tension of isolated arterial segments at resting tone, but relaxed in a concentration-dependent manner the arterial segments preconstricted with 10^{-6} mol/L prostaglandin F_{2n} . These results demonstrate that magnesium sulfate acts as a dilator in the cerebral circulation by acting directly on the cerebral arteries. This could explain, at least in part, its beneficial effects on preeclampsia-eclampsia. (AM J OBSTET GYNECOL 1991;165:1534-8.)

Key words: Magnesium sulfate, cerebral blood flow, cerebral arteries, goat

There is considerable evidence that cerebral vasospasm is involved in the pathogenesis of eclampsia. In fact, the earlier suggestion that the cerebral pathologic findings observed in eclampsia result from periods of vasoconstriction that induce focal necrosis and hemorrhages¹ has now been confirmed by cerebral angiographic and computed tomographic studies.²

In spite of the fact that magnesium sulfate is widely used to prevent and control eclamptic convulsions,^{3, 4} there is considerable controversy regarding its mechanism of action.⁵ Of particular interest is the hypothesis that magnesium could act in a similar way to organic Ca²⁺ entry blockers and thereby relieve cerebral vasospasm and prevent cell damage and cell death.⁶

At present little is known about the effects of magnesium sulfate on the cerebral circulation, because previous reports concerning this subject are limited to in vitro studies. The present work was undertaken to analyze the cerebrovascular effects of magnesium sulfate. Two experimental approaches were used, an in vivo preparation that permits continuous monitoring of cerebral blood flow in the conscious goat and an in vitro

vitro ^b Hos-Depar-

Material and methods

Experimental model in vivo: Measurement of cerebral blood flow. Experiments were performed by following the Guiding Principles in the Care and Use of Animals approved by the Council of the American Physiological Society (1980) and subscribed to by the Scientific Committee of the Centro de Investigación, Hospital "La Fe."

Seven nonpregnant female goats weighing 26 to 44 kg were used in this study. The goat was selected because its unique arterial supply to the brain permits measurement of the entire hemispheric blood flow. The operative procedure for measuring cerebral blood flow has been described previously.8 Briefly, the extracerebral blood flow conducted through the internal maxillary artery is eliminated by ligature and thrombosis of the extracerebral vessels originating in this artery (dental, ethmoidal, ophthalmic, and buccinator arteries). In these conditions virtually all the blood flow from the internal maxillary artery is destined for the brain through the ramus anastomoticus.9 Therefore an electromagnetic flow probe around the internal maxillary artery accurately measures the blood flow to the ipsilateral hemisphere. A catheter was introduced into the temporal artery and permanently fixed to permit injection or infusion of drugs into the internal maxillary artery. A snare-type occluder was placed on the external carotid artery, close to the temporal artery, to obtain zero-flow baselines. The external connecting leads from the flow probe, temporal artery catheter, and occluder were led out subcutaneously and secured to the goat's horn. Catheters were inserted in both the femoral artery and vein to measure the arterial blood pressure and allow blood sampling or infusion of drugs.

Experiments were performed in the conscious animal and started 3 to 5 days after surgery, at which time the goats had fully recovered and were in a steady cardiorespiratory state. The various measurements were taken with the goat in a large cage without restraints, except for a Lucite stock fitting loosely around the neck, which limited forward and backward motion. Once placed in the cage, the animal stood quietly during the experiments and showed no signs of any disturbance. Cerebral blood flow (pulsatile and mean), arterial blood pressure, and heart rate were continuously registered with a Hewlett Packard recorder (model 775&A). Cerebral vascular resistance was calculated as the mean arterial blood pressure in millimeters of mercury divided by cerebral blood flow in milliliters per minute × 100 gm tissue. After termination of the experiments the animals were killed by intravenous injection of 30 mEq potassium chloride, and the whole brain was removed from the skull and weighed for accurate calculation of cerebral blood flow in milliliters per minute × 100 gm of tissue.

The effects of magnesium sulfate (MgSO₄ · 7H₂O) were evaluated during both local intraarterial injections and systemic intravenous infusions. In the first set of experiments, increasing doses (10, 30, 100, and 300 mg) were injected into the internal maxillary artery. The doses were injected through the temporal catheter in a volume of 1 ml saline solution, and the catheter was immediately washed out with an additional 1 ml of the same saline solution. Control injections of saline solution never produced any artifact or subsequent change in cerebral blood flow. In the second set of experiments, increasing doses (0.3, 1, and 3 gm) were infused through the femoral vein catheter by means of a perfusion pump (Hoeschst PP50, rate 1 ml/min) over a period of 15 minutes each.

Experimental model in vitro: Recording of isometric tension. Three additional female goats, previously anesthetized with intravenous 2% thiopental sodium, were killed by intravenous injection of 30 mEq potassium chloride. The whole brain was rapidly removed and the middle cerebral arteries were dissected free and cut into cylindric 4 mm segments. Each segment was set up in a 5 ml organ bath, and two L-shaped stainless steel pins were introduced through the arterial lumen. One pin was fixed to the organ bath wall, and the other was connected to a strain gauge for isometric tension recording. The vascular preparations were

maintained at 37° C in a Ringer-Locke solution gassed with 95% oxygen and 5% carbon dioxide to give a pH of 7.3 to 7.4. The composition of the nutritive medium was as follows: sodium chloride, 120 mmol/L; potassium chloride 5.4 mmol/L; calcium chloride, 2.2 mmol/L; magnesium chloride, 1.0 mmol/L; sodium bicarbonate, 25 mmol/L; and glucose, 5.6 mmol/L. A resting tone of 1 gm was applied, and the arterial segments were allowed to equilibrate during a period of 60 to 90 minutes. Tension was readjusted when necessary and the bath fluid was changed every 15 minutes.

Responses to magnesium sulfate (10^{-5} to 3×10^{-2} mol/L) were obtained in a cumulative manner from arterial segments at resting tone and from arterial segments that had been previously contracted with a single dose of 10^{-5} mol/L prostaglandin $F_{2\alpha}$ (Sigma). The concentration-response curve for magnesium sulfate started once the effect of prostaglandin F2a reached a steady state (active tone).

Analysis of the results. The cerebral blood flow or cerebral vascular resistance values were expressed as a percentage of their respective resting values. For the experiments on intraarterial administration, seven dose-response curves were obtained on seven animals. For the experiments on intravenous infusion, each dose was infused over a period of 15 minutes, and the various parameters were measured at 5-minute intervals (three during infusion plus two additional ones once the pump was stopped). This experiment was repeated seven times on seven goats. Statistical analysis was performed by using the analysis of variance, followed by the least-significant differences test, when appropriate. A probability value of <5% was considered to be significant.

The tension values were expressed either in absolute terms (milligrams) or as a percentage of active tone. Six concentration-response curves in nonpreconstricted arterial segments, and 18 concentration-response curves in preconstricted arterial segments were obtained. For each concentration-response curve, the concentration of magnesium sulfate that produced one half the effect reached with the highest dose ("apparent" EC50) was calculated, since no maximum effect could be reached. The mean EC₅₀ and its confidence limits (95% interval) were calculated by obtaining the mean and confidence limits of the negative logarithms of EC50 values (pD2), because they fit tightly to a normal distribution.

Results

In vivo. Injections of increasing doses of magnesium sulfate (10, 30, 100, and 300 mg) directly into the cerebral circulation of the unanesthetized goat produced immediate, transient, and dose-dependent increases in cerebral blood flow from the dose of 100 mg. No significant changes in arterial blood pressure and heart

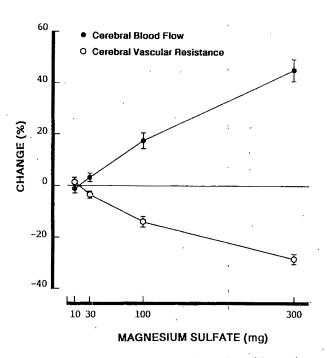

Fig. 1. Effects of intraarterial administration of increasing doses of magnesium sulfate (n = 7) on cerebral blood flow and cerebral vascular resistance in conscious nonpregnant goat. Changes in both parameters are expressed as percentage of their corresponding resting values. Data points represent means \pm SEM.

rate were recorded during the cerebral blood flow increases; therefore dose-dependent reductions in cerebral vascular resistance were obtained. Fig. 1 shows the dose-response curve for magnesium sulfate on both cerebral blood flow and cerebral vascular resistance. Table I shows the effects of 100 mg magnesium sulfate on cerebral blood flow, arterial blood pressure, heart rate, and cerebral vascular resistance.

Intravenous infusions of magnesium sulfate (0.3, 1, and 3 gm/15 min) elicited increases in cerebral blood flow in the unanesthetized goat. Because no significant changes in arterial blood pressure and heart rate were recorded along with the increased cerebral blood flow, reductions in cerebral vascular resistance were obtained. These vasodilatory effects are shown in Fig. 2. Whereas those of 0.3 and 1 gm reached a significant, stable plateau 10 minutes after start of the infusion, that of 3 gm reached it at 5 minutes. These changes remained for 10 minutes after the infusions were stopped. The magnesium plasma levels were determined in one animal at resting state (control) and after completion of the three infusions. The concentrations were 1.7 mg/dl (control), 2.07 mg/dl (0.3 gm), 2..81 mg/dl (1 gm), and 6.67 mg/dl (3 gm).

In vitro. At resting tone, cumulative addition of magnesium sulfate (10^{-5} to 3×10^{-2} mol/L) did not produce sizeable changes in vascular tension. Prostaglan-

din $F_{2\alpha}$ (10⁻⁵ mol/L) produced a sustained contraction (active tone) of 2036 \pm 997 mg (mean \pm SD). In these preconstricted arteries, magnesium sulfate elicited well-defined relaxations that were concentration dependent in magnitude (Fig. 3). The mean EC₅₀ was 5.7 (3.8 to 8.7) \times 10⁻³ mol/L, and the mean maximum effect was $-82.4 \pm 3.6\%$ (percentage of active tone).

Comment

It has long been recognized that vascular spasm may be an important component in the pathogenesis of preeclampsia-eclampsia. Actually, vasospasm has been directly observed in the nail beds, bulbar conjunctivae, and retinal vessels of eclamptic females¹⁰ and signs of coronary artery spasm also have been observed in patients who die of eclampsia. Recent angiographic and computed tomographic studies demonstrate that vascular spasm also affects the brain.²

In the light of this evidence, one may ask about the mechanism of action by which magnesium sulfate prevents and controls eclamptic convulsions. It is tempting to hypothesize that the way in which magnesium relieves cerebral vasospasm is similar to the way organic calcium entry blockers do it. Magnesium has been shown to counter the actions of calcium in many situations, which makes it nature's physiologic calcium blocker¹²; on the other hand, there is now considerable evidence obtained both in vivo13 and in vitro14 that calcium entry blockers inhibit cerebral vasospasm. With this argument, one might expect magnesium to act as a cerebral vasodilator because calcium entry blockers increase cerebral blood flow15 and relax isolated cerebral arteries.14 That hypothesis is the one that we tested in this work.

The results reported here demonstrate unequivocally that, regardless of the route of administration (directly into the cerebroarterial supply or systemically), magnesium sulfate increased cerebral blood flow in the unanesthetized goat with no concomitant changes in arterial blood pressure and heart rate. Our observations on arterial blood pressure and heart rate agree with those reported previously in humans16, 17 and sheep¹⁸ and demonstrate that the vasodilatory action of magnesium sulfate results from a decrease in cerebral vascular resistance. These results resemble those reported previously in pregnant monkeys,17 which show that magnesium sulfate increases uterine blood flow without altering perfusion pressure and cardiac output, which indicates a decrease in uterine vascular resistance. In contrast, blood flow to other organs such as kidney was not changed by magnesium sulfate. Taken together, all of this evidence suggests that magnesium sulfate elicits a redistribution of cardiac output by favoring the irrigation of some organs.

The question arises as to the mechanism by which

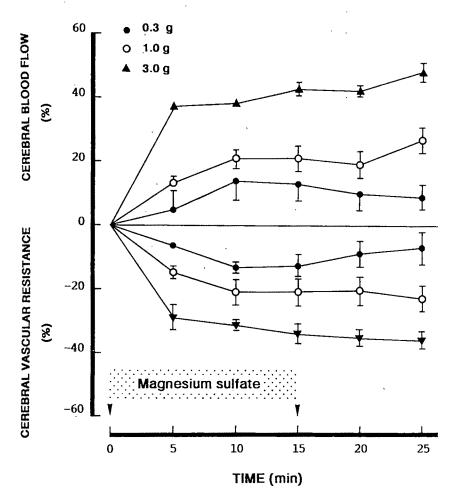

Fig. 2. Effects of intravenous infusion of increasing doses of magnesium sulfate (n = 7) on cerebral blood flow and cerebral vascular resistance in conscious nonpregnant goat. Changes in both parameters are expressed as percentage of their corresponding resting values. Data points represent means ± SEM.

Table I. Effects of magnesium sulfate on cerebral blood flow, arterial blood pressure, heart rate, and cerebral vascular resistance when it is injected into the internal maxillary artery of the unanesthetized goat

	Control	Magnesium sulfate (100 mg)
Cerebral blood flow (ml/min × 100 gm)	· 112.7 ± 14.8	132.4 ± 11.1*
Arterial blood pressure (mm Hg)	118.7 ± 10.8	119.1 ± 6.4
Heart rate (beats/min)	82 ± 9	85 ± 7
Cerebral vascular resistance (mm Hg × 100 gm × min/ml)	1.06 ± 0.11	$0.91 \pm 0.06*$

Values are means ± SD obtained from seven goats.

magnesium sulfate increases cerebral blood flow. A blood-brain barrier for magnesium seems to exist, since cerebrospinal fluid levels of magnesium do not change after administration of magnesium sulfate.19 Therefore it should be accepted that, even if only small amounts of magnesium sulfate diffuse and reach the smooth muscle cells, it acts mainly at the endothelial level. Actually, magnesium sulfate stimulates in vitro the production of prostacyclin (a potent vasodilator) by endothelium of human umbilical vein.20 Because prostacyclin is also produced by and released from the endothelial cells in the brain,21 it seems reasonable to hypothesize that magnesium sulfate acts, at least in part, through that mechanism.

^{*}Significantly different from control values, p < 0.01.

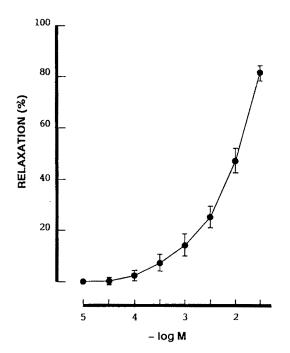

Fig. 3. Concentration-response curve for magnesium sulfate (n = 18) in isolated goat middle cerebral artery preconstricted with prostaglandin $F_{2\alpha}$ (10⁻⁵ mol/L). Relaxation values are expressed as percentage of active tone. Data points represent means \pm SEM.

Our results obtained in vitro show that magnesium sulfate relaxes the isolated cerebral arteries in a concentration-dependent manner. Magnesium has been shown to relax a number of arterial preparations,²² the only exception being femoral arteries, which contract when magnesium sulfate reaches the highest concentrations.⁷ With regard to the cerebral arteries, our results are in close agreement with those obtained in a previous work with feline cerebral arteries,⁷ both in the EC₅₀ and the maximum effect values. The importance of this finding resides in the fact that it confirms the conclusion reached in vivo that magnesium sulfate acts directly on the cerebral arteries and causes them to relax.

In summary, we present experimental evidence obtained both in vivo and in vitro that shows that magnesium sulfate is a dilator of the cerebral circulation. This supplies a rationale for its beneficial effects on preeclampsia-eclampsia, although its ability to relieve cerebral vasospasm should be assessed.

We thank Ms. María del Carmen Tirados and Ms. Lucía Martínez for their technical assistance.

The ability of recombinant tissue plasminogen activator to inhibit post-radical pelvic surgery adhesions in the dog model

F.J. Montz, MD, J. McCabe Fowler, MD, A. John Wolff, BS, Silas M. Lacey, and Margie Mohler, PhD

Los Angeles, California

We investigated the ability of recombinant tissue plasminogen activator to inhibit post–radical pelvic surgery adhesions formation in 40 adult female canines undergoing radical hysterectomy, bilateral salpingo-oophorectomy, omentectomy, resection of pelvic and abdominal peritoneum, and placement of a peritoneal access catheter. Immediately after operation one half of animals received either recombinant tissue plasminogen activator, 1 mg/kg weight, diluted in 9 ml sterile normal saline solution per milligram of the plasminogen activator or 10 ml vehicle per kilogram intraperitoneally every 12 hours for a total of 10 doses. A single control animal died postoperatively of complications of intestinal obstruction. No bleeding abnormalities were noted in either group of animals. Four weeks after surgery, animals underwent reexploration and adhesions were quantified. Adhesion scores for the animals treated with recombinant tissue plasminogen activator (n = 20; mean score, 1.29 \pm 1.97; median, 0.6) were significantly less than for control animals (n = 19; mean score, 4.64 \pm 3.71; median, 3.86; p = 0.03). Whereas recombinant tissue plasminogen activator appears to effectively prevent post–radical pelvic surgery adhesions in this canine model, phase I and II trials in humans will be required to determine safety and clinical benefit. (Am J Obstet Gynecol 1991;165:1539-42.)

Key words: Post-radical pelvic surgery adhesions, recombinant tissue plasminogen activator

Radical pelvic surgery, when used in the treatment of patients with gynecologic malignancies, has many well-defined side effects. These include, but are not limited to, the following: intestinal and ureteral obstruction, bowel dysfunction, fistula formation, and chronic abdominal-pelvic pain. The development of postsurgical adhesions also interferes with the intraperitoneal distribution of fluids. This interference limits the use of many intraperitoneal treatment modalities.^{1, 2}

Many potential adhesion-preventing agents have been investigated throughout the history of surgery.³ None, including the more recently advocated barrier methods, have demonstrated effectiveness at limiting adhesion formation after a radical pelvic resection similar to that performed in patients treated for advanced ovarian malignancies.^{4, 5} Human recombinant tissue plasminogen activator is a thrombolytic agent that binds to fibrin and activates plasminogen to plasmin.⁶ This plasmin is the primary enzyme responsible for the pro-

Montz, MD, Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, UCLA Center for Health Sciences, 10833 Le Conte, Los Angeles, CA 90024-1740. 6/1/31297 teolytic degradation of fibrin. The persistence of excessive fibrin has been proposed as a pathophysiologic basis of adhesion formation. Recent investigations have suggested that recombinant tissue plasminogen activator, when applied topically, may be effective in limiting postoperative adhesion development. So as to confirm or refute these findings, we investigated the ability of recombinant tissue plasminogen activator to limit the formation of postoperative abdominal-pelvic adhesions when used in an animal model that underwent a radical resection of the pelvic viscera and peritoneum.

Material and methods

Forty adult female mongrel canines that had not previously undergone intraperitoneal surgery were used. Animals were housed at the University of California at Los Angeles vivarium. All animal procedures were performed in accordance with the standards described in the National Institutes of Health Guide for the Care and Use of Laboratory Animals, in compliance with the Federal Animal Welfare Act.

Mean animal weight was 21 kg (range, 18.5 to 23.5). Animals were quarantined for 10 days, during which time they were allowed access to water and chow ad libitum, then fasted for 24 hours before surgery. After induction of general endotracheal anesthesia with pentobarbital sodium, 10 mg/kg, and assisted ventilation with a volume ventilator and an Fio₂ of 40%, animals

underwent exploratory celiotomy. The animals' anterior abdominal wall, right chest wall, and back to the level of the scapula were shaved and prepped with a standard povidone-iodine solution. With the animals in a left lateral decubitus position, with an aseptic technique, a 1 cm stab incision was made below the scapula on the right side. Through this incision an intraperitoneal catheter was tunneled under the skin of the back and chest wall, then brought through the skin immediately below the right costal margin. The animals were repositioned in a supine position, reprepped, and draped with sterile technique. The abdomen was sharply opened by a midline incision from the umbilicus to the symphysis pubis. Intraperitoneal exploration was performed, and a total radical abdominal hysterectomy, bilateral salpingo-oophorectomy, and infracolonic omentectomy were performed. The pelvic peritoneum was removed along with the peritoneum from the lower one third of the anterior abdominal wall. Surgery was performed with bipolar electrocautery, both for cutting and for coagulation of individual bleeding sites. Free vascular pedicles were ligated with 2-0 silk ties. The vaginal cuff was closed with interrupted 2-0 chromic sutures.

Before closing the abdomen, a subcutaneous tunnel was made and the intraperitoneal catheter brought from the subcostal site to the most inferior aspect of the incision. The catheter was then bluntly brought through the abdominal wall fascia and placed into the peritoneal cavity. Adequate catheter length was left intraperitoneally to allow the tip to lie in the cul-de-sac. After assuring hemostasis and a correct sponge and needle count, the anterior abdominal wall was closed with I-0 Maxon (Davis and Geck, Inc., Manati, Puerto Rico) sutures in a running Smead-Jones technique. The skin was closed with subcuticular 3-0 Dexon (Davis and Geck) sutures. The stab wounds on the chest and abdominal wall were closed with 3-0 Dexon sutures in an interrupted manner. The catheter was secured at the site of entrance into the subcutaneous tunnel with 3-0 Prolene (Ethicon, Inc., Somerville, N.J.).

In a randomized manner, after the completion of surgery, the animals were divided into two groups. One half of the animals received a dose of 1 mg/kg of recombinant tissue plasminogen activator (Activase, Al-

teplase, 1 mg/ml supplied by Genentech Inc., South San Francisco), which was diluted with 9 ml of sterile normal saline solution for each milligram of recombinant tissue plasminogen activator, intraperitoneally every 12 hours for a total of 10 doses. This dose and dosing schedule have been shown to have a maximal adhesion prevention effect in a rabbit uterine horn model.11 The initial intraperitoneal bolus was given immediately after completion of surgery. Control animals were similarly treated with 10 ml of normal saline solution (inert vehicle) per kilogram intraperitoneally every 12 hours for a total of 10 treatments. After the tenth instillation of either recombinant tissue plasminogen activator solution or vehicle alone, the catheters were removed and the exit site sutured closed with 3-0 Dexon. The length of treatment, 5 days, was selected in light of the fact that organization of fibrinous adhesions does not take place until that time12 and that by increasing the duration of treatment to 5 days a maximum adhesion prevention effect can be obtained.11

The animals were observed in the postoperative recovery area for 24 hours after surgery and recovery from general anesthesia. During that period, they were allowed free access to water, but food was withheld. After the immediate postoperative recovery, the animals were returned to the general dog run and allowed access to food and water as desired. All animals were observed on a twice-daily basis. Abdominal incisions and catheter sites were evaluated for signs of bleeding, infection, or breakdown. The animals also were observed for signs of abnormal bleeding, gastrointestinal or urinary dysfunction, and general recovery and activity levels.

Four weeks after the initial surgery, anesthesia followed by euthanasia was effected with intravenous pentobarbital sodium (100 mg/kg). While under anesthesia, but before being killed, the animals underwent exploration through a supraumbilical incision. The incision was extended caudally and adhesions were quantified and scored for the anterior abdominal wall incision and pelvis. Adhesion scoring was performed by a surgeon who was blinded to the treatment (recombinant tissue plasminogen activator or vehicle) that the animal received. The pelvis was divided into four quadrants with the vaginal apex dividing the pelvis into anterior-posterior and lateral halves. Adhesions were recorded as the percentage of surface area covered in each of the five regions (abdominal wall incision and four pelvic quadrants). Adhesions were scored according to type (Table I). Abnormal findings (abscess formation, lymphadenopathy, foreign body reaction, etc.) and the integrity of the wound were similarly recorded.

With a modification of a previously reported method, 18 adhesion scores for each of the five locales

Table II. Adhesion scores

	Grade	I	Grade	II	Grade .	III	Total	!
	Mean	Median	Mean	Median	Mean	Median	Mean	Median
Recombinant tissue plasminogen activator— treated animals (n = 20)	0.29 ± 0.25	0.24	0.19 ± 0.38	. 0	0.81 ± 1.20	0.31	1.29 ± 1.97	0.60
Vehicle-treated animals (n = 19)	0.63 ± 0.28	0.64	0.75 ± 0.77	0.61	3.17·± 2.69	2.82	4.64 ± 3.71	3:86
p Value	0.017	7	0.048	3	0.01		0.03	

were calculated. This was done by multiplying the assigned points for each adhesion grade by the percentage of the surface area involved with that specific grade of adhesion. A value of 1.00 was used to equal 100% involvement. By summing the data from all five locales, a grade-specific adhesion score and a total adhesion score were obtained. Statistical analysis was performed on log transformation of the adhesion scores with the Student t or Wilcoxon nonparametric test, where indicated.

Results

There were no intraoperative deaths in this series. One control animal did die on the eighth postoperative day; necropsy demonstrated extensive intraperitoneal adhesions, a small bowel obstruction, and a necrotic, perforated segment of ileum. No bleeding abnormalities were noted in either the experimental or control animals. However, serum recombinant tissue plasminogen activator levels and coagulation studies were not performed. No abscesses, fistulas, or fascial defects or hernias occurred in either group.

Adhesion scores for the recombinant tissue plasminogen activator-treated animals (n = 20; mean adhesion score, 1.29 ± 1.97 ; median, 0.6) were significantly less than for control animals (n = 19; mean adhesion score, 4.64 ± 3.71 ; median, 3.86; p = 0.03). This finding was consistent for all types and locales of adhesions (Table II).

Comment

Postsurgical remesothelialization of the peritoneal cavity is the result of a complex series of reactions.14 Peritoneal injuries associated with ischemia, hemorrhage, foreign body, or infection are known to disrupt the equilibrium between the normal fibrin deposition and fibrinolysis, thus increasing adhesion development.15-18 It is this latter phenomenon that has stimulated investigators to perform studies to determine if locally administered recombinant tissue plasminogen activator could be successful at curtailing postsurgical adhesion formation.8-10

The ability of recombinant tissue plasminogen acti-

vator to limit adhesion formation is probably due to its success at reestablishing the normal equilibrium of fibrin deposition and fibrinolysis by increasing the local level of plasminogen activator activity. Multiple investigators have proposed that this effect is the most important link in a final common pathway by which many antiadhesion agents are able to decrease postsurgical adhesion formation.19.20

High doses of recombinant tissue plasminogen activator administered as a thrombolytic agent have been shown to cause decreases in systemic fibrinogen and increases in fibrin degradation products.21 Possible complications from the intraperitoneal use of recombinant tissue plasminogen activator, such as excessive bleeding and the prevention of wound healing, were not observed in this study. However, future studies will be needed to accurately assess coagulation and hematologic parameters. The fact that no animals evidenced any apparent bleeding abnormality may be explained by the fact that there could be fairly rapid absorption of the recombinant tissue plasminogen activator into the systemic circulation with subsequent rapid clearance from the circulation or that degradation may occur in the peritoneal cavity. Similarly, because recombinant tissue plasminogen activator preferentially activates fibrin-bound plasminogen,22 the generation of free plasmin in the peritoneum would be minimized and the potential for any bleeding abnormality limited. Although no animals in either group were completely adhesion-free, a significant decrease was seen in all grades of adhesions in the recombinant tissue plasminogen activator-treatment group. Theoretically, optimization of dose and treatment duration may improve the reduction of adhesions with this therapy.

The discovery that recombinant tissue plasminogen activator has a demonstrated capacity to limit adhesion formation in this unique model has stimulated speculation that it may be effective when given intraperitoneally in women who have undergone radical oophorectomy and resection of pelvic and lower abdominal peritoneum as part of the treatment for metastatic ovarian malignancies. Should such an effect be demonstrated, it would open the way to increased use of adjuvant intraperitoneal treatment modalities immediately after surgery. It is during this period when tumor volume is the lowest and cell growth fraction the highest and thus may be the time when any residual tumor is most susceptible to cytotoxic therapy.

At present, no agent has been demonstrated to be effective in either the animal or human model at limiting adhesions after radical pelvic surgery. In light of this fact, adhesion prevention agents are not usually used by the radical pelvic surgeon, although their benefit beyond that of facilitating the use of intraperitoneal therapeutic agents is self-evident (decrease in postoperative bowel obstructions, ureteral obstructions, chronic pelvic pain syndromes, etc.).

In conclusion, it is important to remember that our results come from a limited animal trial. At present there are no available data regarding the safety of intraperitoneal recombinant tissue plasminogen activator in humans; phase I and phase II clinical studies will be needed to thoroughly evaluate the safety and risks of intraperitoneal recombinant tissue plasminogen activator in the prevention of post—radical pelvic surgery adhesion formation in human subjects.

We thank Dr. Peter D. Christenson, of the Department of Biomathematics, University of California, Los Angeles, for his invaluable assistance with preparation and statistical review of the data presented in this manuscript. We also thank Genentech, Inc., for supplying the recombinant tissue plasminogen activator used in this study.

Effects of magnesium and terbutaline on contractility and K⁺ uptake in isolated human uterine muscle

Kristjar Skajaa, MD,² Maria E. Everts, PhD,⁵ Torben Clausen, MD, PhD,⁵ and Axel Forman, MD, PhD²

Aarhus, Denmark

Mg⁺⁺ (3 and 6 mmol/L), the β_2 -adrenergic agonist terbutaline (1 and 10 μ mol/L), and dibutyryl cyclic adenosine 5'-monophosphate (0.1 and 1 mmol/L) suppressed spontaneous activity and the increase in contractile activity induced by ouabain or K⁺-free buffer in isolated human pregnant myometrium. The ouabain-suppressible rubidium 86 or potassium 42 uptake was unaffected by the presence of Mg⁺⁺ (3 and 6 mmol/L), the β_2 -adrenergic agonist terbutaline (1 and 10 μ mol/L), or dibutyryl cyclic adenosine 5'-monophosphate (1 mmol/L). However, loading of the strips with Na⁺ and incubation in high K⁺ induced a fivefold increase in rubidium 86 uptake. On the basis of these flux rates, our previous data on the total concentration of sodium-potassium pumps in the human myometrium, and an estimated maximum transport rate of the sodium-potassium pump of 8900 K⁺ ions per minute at 30° C, it could be calculated that the sodium-potassium pump in the Na⁺-loaded strips reached around 80% of its maximal rate. Taken together, these results showed that the relaxant effects of Mg⁺⁺, terbutaline, and dibutyryl cyclic adenosine 5'-monophosphate on human myometrium are not due to a stimulation of active sodium-potassium transport. (AM J OBSTET GYNECOL 1991;165:1543-51.)

Key words: Human myometrium, Mg⁺⁺, β₂-adrenergic receptor agonist, cyclic adenosine 5'-monophosphate, sodium, potassium, adenosine triphosphatase

The β₂-adrenergic receptor agonist terbutaline is widely used as a tocolytic agent for the treatment of premature labor contractions, but it is well known that it is associated with several side effects. Since the late 1950s, when it was recognized that magnesium sulfate possesses tocolytic effects, the use of this agent has increased in the treatment of premature contractions. Several studies have compared the effectiveness of terbutaline and magnesium sulfate as tocolytic agents. No major differences concerning their ability to arrest labor contractions were found, but magnesium sulfate seemed to produce fewer side effects.

The exact mechanisms of action of Mg⁺⁺ and terbutaline on the myometrium are not clear. Experimental studies on human myometrium⁷⁻¹⁰ have demonstrated that selective β_2 -adrenergic receptor agonists inhibit uterine contractions, and it is generally believed that these effects are mediated through an increase in the intracellular concentration of cyclic adenosine 5'-monophosphate (cAMP).¹¹ Scheid et al.^{12, 13} found that

active electrogenic sodium-potassium transport in toad stomach smooth muscle was stimulated by the β -adrenergic agonist isoproterenol and suggested that the ensuing decrease in intracellular Na+ favored Na+Ca++ exchange, leading to decreased intracellular Ca++ and relaxation. A similar mechanism of action for β_2 -adrenergic receptors has been suggested in other smooth muscle preparations. However, in rat uterine muscle there is no reported evidence that the relaxant effects of isoproterenol should be due to a stimulation of the sodium-potassium adenosine triphosphatase. $^{18-21}$

The mechanism of action of Mg^{++} on human myometrium is not yet clarified. In rat myometrium Mg^{++} was shown to potentiate the actions of β_2 -adrenergic receptor agonists, 22 and in vascular smooth muscle from animals $^{23,\ 24}$ and man $^{25,\ 26}$ and in human nonpregnant myometrium 27 Mg^{++} was shown to interfere with Ca^{++} entry through the cell membrane and with intracellular Ca^{++} mobilization. Optimum function of the sodium-potassium adenosine triphosphatase depends on the presence of Mg^{++} at low concentrations, but whether Mg^{++} in concentrations reached during therapy (2 to 4 mmol/L) may influence active sodium-potassium transport is not known.

In our study we have examined the possible effects of Mg⁺⁺, terbutaline, and dibutyryl cAMP on active sodium-potassium transport in human pregnant myometrial strips obtained at term. Furthermore, the effects of these agents on contractile activity caused by

sodium-potassium adenosine triphosphatase inhibition by K⁺-free buffer or ouabain were studied.

Material and methods

The study was approved by the local ethical committee according to the Helsinki Declaration II. All patients gave informed consent. In 10 pregnant women a biopsy of the uterine muscle was performed in the upper part of the isthmic incision at elective term cesarean section performed because of breech presentation (n = 5), genital herpes (n = 1), or previous cesarean section (n = 4). In two instances a biopsy specimen was obtained from the fundus region as well. The specimens were immediately placed in ice-cold Krebs-Ringer solution and transported to the laboratory. Under a stereomicroscope, smooth muscle strips (diameter, 1 mm; length, 4 to 5 mm) were dissected along the fiber direction with microscissors. To ensure comparability the strips prepared from each biopsy specimen were used for measurement of isometric tension and ion fluxes.

Isometric tension. The contractile performance of the myometrial strips was assessed essentially as previously described.28 By means of silk sutures (6-0) at either end, the preparations were mounted horizontally between two small, L-shaped hooks in 5 ml thermostatregulated organ baths (37° C) containing Krebs-Ringer bicarbonate buffer continuously gassed with a mixture of 95% oxygen and 5% carbon dioxide, resulting in a final pH of 7.4. One of the hooks was attached to a force transducer (Grass Ft 03) for measurement of isometric tension, and the other was connected to a sledge, which allowed adjustment of length of the strip. Tension was recorded by a six-channel Beckman R611 polygraph. A small preload (0.1 mN) was applied to the strips, and the distance between the two knots of the silk sutures was measured by a stereomicroscope equipped with an ocular micrometer and was defined as the resting length. Adjustment was then performed to secure a distance between the two knots of 160% of the resting length. In separate length-tension experiments this was found to be optimum for mechanical performance (unpublished data). After the equilibration period, contractions were repeatedly induced by K⁺ (126 mmol/L) until reproducible (<10% variation between two successive contractions), and then the experiments commenced.

Ion fluxes

Potassium 42 or rubidium 86 uptake: All experiments were carried out with myometrial strips weighing 15 to 20 mg. Incubations took place at 30° C under continuous gassing with a mixture of 95% oxygen and carbon dioxide in a volume of 2 to 3 ml Krebs-Ringer bicarbonate buffer (pH 7.4) containing ⁴²K (0.5 μCi/ml) or ⁸⁶Rb (1 μCi/ml). Most experiments were carried out

with 86Rb. This is a tracer for potassium, but because of its much longer half-time, it is more convenient than ⁴²K. Immediately after preparation, the strips were equilibrated in the standard incubation medium for at least 30 minutes. This was followed by preincubation for 15 minutes in the absence or presence of ouabain (I mmol/L). This concentration has earlier been shown to allow full saturation of all tritium-ouabain binding sites in the human myometrium.29 Thereafter the myometrial strips were incubated for periods lasting between 2 and 60 minutes without or with ouabain (1 mmol/L) present. Incubation was followed by washout four times for 15 minutes each at 0° C in Na+-free Tris-sucrose buffer (Tris hydrochloride, 10 mmol/L; sucrose, 263 mmol/L; pH 7.4) so as to remove extracellular Na+ and tracer. The strips were then blotted, weighed, homogenized in 2 ml of 0.3 mol/L trichloroacetic acid, and taken for counting of 42K or 86Rb activity by Cerenkov radiation.

In some experiments myometrial strips were loaded with Na+ according to a method earlier developed.30 Incubation three times for 30 minutes in buffer in which all Ca++, Mg++, and K+ had been replaced by an equimolar amount of Na+, and 0.5 mmol/L ethylene glycol-bis (β-amino ethyl ether) N,N,N',N'-tetraacetic acid added so as to cause further reduction in extracellular Ca++. This was followed by incubation for 30 minutes in the same buffer with the addition of sodium chloride (100 mmol/L), and a 15-minute wash in normotonic Ca++-, Mg++-, and K+-free buffer containing 0.5 mmol/L ethylene glycol-bis (β-amino ethyl ether) N,N,N',N'-tetraacetic acid with or without ouabain (1 mmol/L). As calculated from measurements of the total Na+ content and the carbon 14-sucrose space, this procedure resulted in intracellular Na+ and K+ concentrations of 136 and 27 mmol/L, respectively. Hereafter, the strips were incubated for 10 minutes in the absence or presence of ouabain (1 mmol/L) in buffer in which all Na+ was replaced by K+ (151.2 mmol/L). Finally, the strips were washed, weighed, homogenized, and counted as described above. The ouabain-suppressible 42K or 86Rb uptake was calculated as the difference between the values obtained in the absence and in the presence of ouabain (1 mmol/L).

⁴²K efflux. This was measured essentially as described earlier for rat soleus muscle.³¹ After equilibration, the strips were preloaded for 60 minutes at 30° C in standard buffer containing ⁴²K (2 μCi/ml). The washout of ⁴²K was followed by transferring the strips through a series of tubes without isotope. Thereafter the strips were blotted, weighed, homogenized in 0.3 mol/L trichloroacetic acid and taken for counting of ⁴²K activity. By adding successively the activity in the washout tubes to that in the strips by the end of the experiment, the ⁴²K activity in the strips at each transfer was calculated.

On the basis of these values the fractional loss of 42K was calculated for each washout period.

 Na^+-K^+ contents. Strips were homogenized in 2 ml trichloroacetic acid (0.3 mol/L) and centrifuged. The Na+-K+ contents of these extracts were determined with a Radiometer FLM3 flame photometer with lithium as internal standard.92

Statistics. For ion flux experiments, after homogeneity of variance was ascertained, significance of difference was assessed by one-way analysis of variance or by the two-tailed t test for groups of nonpaired observations with a level of significance of 0.05.

Solutions. Krebs-Ringer bicarbonate buffer contained the following: 120.2 mmol/L sodium chloride, 25.1 mmol/L sodium bicarbonate, 4.7 mmol/L potassium chloride, 1.2 mmol/L potassium orthophosphite, 1.2 mmol/L magnesium sulfate, 1.3 mmol/L calcium chloride, and 5 mmol/L D-glucose. In K+-rich Krebs-Ringer bicarbonate buffer for tension measurement (126 mmol/L K+), sodium chloride was replaced by an equimolar amount of potassium chloride. In K+-rich Krebs-Ringer bicarbonate buffer for ion flux studies (151.2 mmol/L K+), both sodium chloride and sodium bicarbonate were replaced by equimolar amounts of potassium chloride and potassium bicarbonate, respectively.

Drugs. Drugs used were terbutaline (Bricanyl, Draco), dibutyryl cAMP N6-21-0-dibutyryladenosine 3:'5:'-cyclic monophosphate (Sigma), ouabain (G-strophanthin, Merck), forskolin (Sigma), and insulin (Novo-Nordisk).

Results

Isometric tension. Only myometrial strips that exhibited spontaneous contractions (about 95% of the preparations) were used for these experiments. Regular spontaneous activity consisting of phasic contractions, sometimes with superimposed minor oscillations at the peak, developed within I hour of equilibration with a frequency of two to three contractions per 10 minutes (Fig. 1, a). The pattern of contractile activity showed interindividual variation, therefore spontaneous activity and the effects of all agents tested are shown for preparations obtained from six different donors. Depolarization of the myometrial strips with a K+rich Krebs-Ringer buffer (126 mmol/L K+) produced a contraction consisting of a rapidly developing peak followed by a second phase with a steady tension amounting to about 20% of the initial peak. The maximum amplitude of the spontaneous contractions was about 90% of the K+-induced peak amplitude. The amplitude of tension produced by the spontaneous contractile activity varied between 4 and 20 mN.

Fig. 1 shows the effects of Mg++, terbutaline, and dibutyryl cAMP on the spontaneous contractile activity. Mg++ (added to final concentrations of 3 and 6 mmol/L) invariably abolished the contractions, irre-

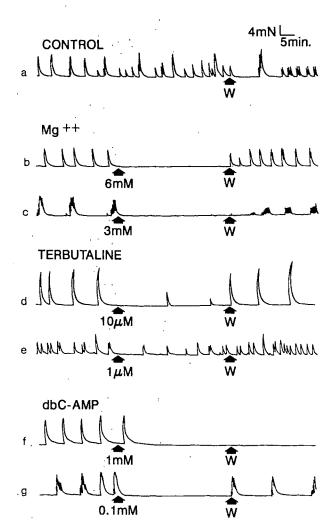

Fig. 1. Representative traces of effects of Mg++ (3 and 6 mmol/L), terbutaline (1 and 10 μmol/L), and dibutyryl cAMP (dbcAMP) (0.1 and 1 mmol/L) on spontaneous contractile activity in human myometrial strips. Traces (a to h) represent recordings from preparations from six different women. In each experiment with tissue from one subject all substances (Mg++, terbutaline, dibutyryl cAMP) were tested. The preparations were mounted horizontally between two small, L-shaped hooks in 5 ml organ baths (37° C), and isometric tension was recorded. W, Wash with Krebs-Ringer buffer. Time scale and scale of contractile response in millinewtons (10⁻⁸ newtons) are indicated at top right corner.

spective of the pattern of the activity (n = 6). The myometrial activity was rapidly reestablished when the bathing solution was replaced by buffer containing 1.2 mmol/L Mg $^{++}$ (Fig. 1, b and c). In five of six preparations tested, terbutaline (1 and 10 µmol/L) caused on average 75% and 90% reduction of the frequency of the contractions, respectively, and the amplitude was clearly diminished (Fig. 1, d and e). At 0.1 µmol/L, terbutaline only slightly (about 10% to 20%) reduced the amplitude, whereas the frequency of the contractions was unaffected (not shown). In only one of the

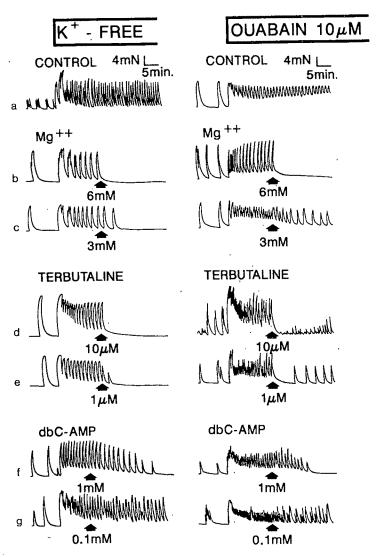

Fig. 2. Representative traces of contractile activity in human myometrial strips after replacement of Krebs-Ringer buffer by K⁺-free buffer (a, left) or addition of ouabain (10 μ mol/L) to the organ bath (a, right). Effects of Mg⁺⁺ (3 and 6 mmol/L), terbutaline (1 and 10 μ mol/L), and dibutyryl cAMP (dbcAMP) (0.1 and 1 mmol/L) on contractile activity induced by K⁺-free buffer or ouabain are shown in traces b to h. Traces a to h represent recordings from preparations from four different women. In each experiment with tissue from one subject all substances (Mg⁺⁺, terbutaline, dibutyryl cAMP) were tested. Time scale and scale of contractile response in millinewtons (10⁻³ newtons) are indicated at top right corner.

preparations terbutaline failed to affect the spontaneous contractile activity and the contractions induced by K^+ -free buffer or ouabain (see below). The myometrial activity was invariably restored after wash in Krebs-Ringer buffer (Fig. 1, d and e). Dibutyryl cAMP (1 mmol/L) irreversibly turned off spontaneous myometrial contractile activity (Fig. 1, f). Dibutyryl cAMP, 0.1 mmol/L, abolished the contractions in all instances (n = 6), but the activity was immediately restored after wash with Krebs-Ringer buffer (Fig. 1, g). In about 50% of the preparations the washing procedure induced a change of the pattern of the contractile activity as compared with the initial pattern. This was seen both in

control preparations and in preparations where Mg⁺⁺, terbutaline, or dibutyryl cAMP had been added and probably reflects a shift in pacemaker cell activity in the myometrial strips.

When normal Krebs-Ringer buffer (K⁺, 5.9 mmol/L) was substituted by a K⁺-free buffer, the contractile activity of the myometrial strips was considerably increased. The response consisted of transient tonic contractions with superimposed phasic contractions, continuing into a steady state with phasic contractile activity; sometimes with a minor elevation of basic tension (Fig. 2, left, n = 6). When a steady state had been achieved after initial stimulation of the con-

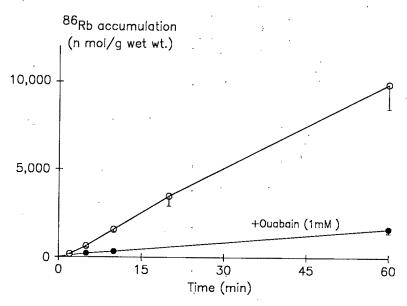

Fig. 3. Time course of ⁸⁶ Rb uptake in absence and presence of ouabain in human myometrial strips. Strips were equilibrated for 30 minutes at 30° C in Krebs-Ringer buffer and preincubated for 15 minutes in absence or presence of ouabain (1 mmol/L). This was followed by incubation lasting from 2 to 60 minutes in buffer containing ⁸⁶Rb (1 μCi/ml) without or with ouabain (1 mmol/L). Strips were then washed four times for 15 minutes each time at 0° C in Na⁺-free Tris-sucrose buffer. Thereafter, strips were blotted, weighed, homogenized in 2 ml trichloroacetic acid (0.3 mol/L), and taken for counting of ⁸⁶Rb activity by Cerenkov radiation. Each point represents means of 12 to 20 observations with *bars* indicating SE where this exceeds size of symbols. Data were obtained in five independent experiments with tissue from five different subjects. In each experiment at least two time points were measured.

tractile activity by K⁺-free buffer, as shown in Fig. 2, Mg⁺⁺ (3 and 6 mmol/L) in all instances and terbutaline (1 and 10 μ mol/L) in five of six preparations abolished the contractions (Fig. 2, left, b to e, n=6). However, terbutaline (0.1 μ mol/L) did not affect the activity induced by the K⁺-free buffer. Dibutyryl cAMP (1 mmol/L) also abolished the contractions induced by K⁺-free buffer, but the effect of this compound developed more slowly, and at 0.1 mmol/L dibutyryl cAMP had no effect (Fig. 2, left, f and g, n=6).

Ouabain (10 µmol/L) caused a contraction consisting of an initial peak and a second phase with maintained tension and superimposed phasic contractions (Fig. 2, right). Both the tonic component and the phasic contractions were invariably abolished by 6 mmol/L Mg++ (Fig. 2, right, b, n = 6). Mg^{++} , 3 mmol/L, reduced only the amplitude and the frequency of the phasic contractions (Fig. 2, right, c, n = 6). In all preparations but one, terbutaline (I and 10 µmol/L) transiently abolished the increased tone and the phasic contractions induced by ouabain (n = 6). Phasic contractile activity with varying amplitude and frequency then reappeared within 5 to 8 minutes (Fig. 2, right, d and e). At a concentration of 1 mmol/L dibutyryl cAMP gradually (within 10 minutes) abolished the contractile activity induced by ouabain in all preparations (n = 6), whereas 0.1 mmol/L had no significant effects (Fig. 2, right, f and g).

K⁺ uptake and efflux. The time course of the ⁸⁶Rb uptake in myometrial strips incubated in the absence or presence of ouabain (1 mmol/L) is shown in Fig. 3. In both cases 86Rb uptake approached a linear function of time. 86Rb uptake in the presence of ouabain amounted to 12% to 35% (60 and 5 minutes, respectively) of the total 86Rb uptake, indicating that the major part (65% to 88%) of the K+ uptake in this tissue is mediated through the sodium-potassium pump. The ouabain-suppressible K+ uptake (calculated from the 10-minute values) amounted to around 125 nmol/gm wet weight per minute. When ouabain-suppressible K+ uptake was measured with 42K, roughly the same value was obtained (Table I). This indicated that both 86Rb and 42K can be used to quantify the sodium-potassium pump-mediated K+ uptake. Furthermore, from Table I it can be seen that neither Mg++ (6 mmol/L) nor terbutaline (1 to 10 µmol/L) caused any significant changes in the ouabain-suppressible 42K or 86Rb uptake during an incubation period of 10 minutes. This implied that neither Mg++ nor terbutaline had any effect on the sodium-potassium pump-mediated K⁺ uptake. However, in the initial phase the 86Rb uptake as expressed per minute was somewhat reduced, presumably reflecting diffusional delay for the access of isotope to interstitial space (see also Table II).

The study of Daniel et al. 18 suggested that the effect of isoproterenol on 12 K uptake in rat myometrium be-

Table I. Effects of Mg⁺⁺ and terbutaline on ouabain-suppressible ⁴²K and ⁸⁶Rb uptake in human pregnant myometrial strips

	Ouabain-suppressible ¹² K uptake (nmol/gm wet wt/min)	Ouabain-suppressible ⁸⁶ Rb uptake (nmol/gm wet wt/min)		
Control	$109 \pm 22 \ (n = 12)$	$90 \pm 19 (n = 12)$		
Mg ⁺⁺ (6 mmol/L) Terbutaline	$116 \pm 26 \ (n = 12)$	$85 \pm 10 \ (n = 12)$		
l μmol/L	$109 \pm 15 \ (n=4)$	ND		
10 μmol/L	$139 \pm 36 \ (n=8)$	$86 \pm 15 (n = 12)$		

Values are mean \pm SE with the number of observations in parentheses. Myometrial strips weighing around 20 mg were prepared. ⁴²K and ⁸⁶Rb uptake was measured in the absence or presence of ouabain (1 μ mol) during 10 minutes of incubation followed by washout four times for 15 minutes each at 0° C as described in legend to Fig. 3. Tissue was obtained from four subjects. From each subject a group of four control specimens was tested against either Mg⁺⁺ (6 μ mol/L) or terbutaline (1 or 10 μ mol/L). None of the effects observed gained statistical significance (p > 0.10). ND, Not determined.

Table II. Effects of terbutaline on time course of ⁸⁶Rb uptake in absence and presence of ouabain in human pregnant myometrial strips

Control	$209 \pm 21 (n = 8)$	$184 \pm 21 \ (n = 8)$
Terbutaline (10 µmol/L)	$197 \pm 14 \ (n = 8)$	$173 \pm 14 \ (n = 8)$

Values are mean \pm SE with the number of observations in parentheses. Strips weighing around 20 mg were prepared. ⁸⁶Rb uptake was measured in the absence or presence of ouabain (1 mmol/L) with incubations lasting between 2 and 60 minutes followed by washout four times for 15 minutes each at 0° C as described in legend to Fig. 3. Tissue was obtained from two subjects, and the results are pooled from experiments on tissue specimens from both subjects. None of the effects observed gained statistical significance (p > 0.05). ND, Not determined.

came more evident after 60 minutes of incubation. On the other hand, the effect of isoproterenol on active sodium-potassium transport in another smooth muscle preparation¹⁵ was maximal within 5 minutes of exposure. However, in our experiments there was no effect of terbutaline (10 µmol/L) on ⁸⁶Rb uptake in the absence or presence of ouabain, as measured during incubation periods of 2, 5, 10, or 60 minutes (Table II).

It has been proposed that β_2 -adrenergic receptor activation leads to opening of K⁺ channels, which could induce hyperpolarization and ensuing relaxation³³; therefore the effect of terbutaline (10 μ mol/L) on the fractional loss of ⁴²K from the myometrial strips also was assessed, but no significant change was observed (n = 3). Mg⁺⁺ (6 mmol/L) produced no significant effect (n = 3), but ouabain (1 mmol/L) increased the fractional loss of ⁴²K by 106% within 15 minutes (p < 0.001, n = 3) (data not shown). From the fractional loss of K⁺ at rest and the K⁺ content by the end of the experiment in the control strips, the absolute

rate of K⁺ efflux could be calculated. This amounted to $0.0038~\text{min}^{-1} \times 40.4~\mu\text{mol/gm}$ wet weight = 154 nmol/gm wet weight per minute (i.e., a value not far below the total K⁺ uptake, indicating that the strips were in steady state).

Table III shows the results of experiments where agents that are known to stimulate K⁺ uptake in skeletal muscle (insulin, dibutyryl cAMP)^{31, 34} or to produce a rise in cellular cyclic adenosine 5′-monophosphate (forskolin)³⁵ were tested. None of the agents, insulin (100 mU/ml), forskolin (10 μmol/L), or dibutyryl cAMP (1 mmol/L), significantly increased ⁸⁶Rb uptake.

Several of the agents known to stimulate active sodium-potassium transport in skeletal muscle failed to stimulate ⁸⁶Rb uptake; therefore it was important to examine whether the sodium-potassium pump of the myometrium could be stimulated by Na⁺ loading. In Na⁺-loaded strips exposed to K⁺-rich buffer (151.2 mmol/L K⁺), the ouabain-suppressible ⁸⁶Rb uptake amounted to 525 ± 136 (n = 12) nmol/gm wet weight per minute (i.e., a fivefold higher rate than the basal values given in Table I).

To see whether K+ uptake varied in the different parts of the myometrium, 86Rb uptake was compared in strips prepared from biopsy specimens of the isthmic and fundus region. The basal rate of 86Rb uptake was similar in both parts of the myometrium, and no differences concerning the effects of Mg++ (6 mmol/L), terbutaline (10 µmol/L), or dibutyryl cAMP (1 mmol/L) on the 86Rb uptake could be detected (data not shown).

Comment

This study was undertaken to determine whether the effects of Mg++ and the β_2 -adrenergic receptor agonist terbutaline on the contractile performance of human pregnant myometrium could be related to effects on sodium-potassium-adenosine triphosphatase activity.

Although with some variation between tissue from different subjects, the amplitudes and frequencies of the spontaneous contractile activity of the myometrial strips used in this study were similar to those previously reported.7-10, 28

The results show that terbutaline, in a concentrationdependent way, inhibited the spontaneous contractions up to complete suppression of the activity at a concentration of 10 µmol/L. The exact mechanism for the action of the β₂-adrenergic receptor agonists has yet to be established, but it is generally accepted that the receptor occupation results in activation of adenylate cyclase, which increases the intracellular content of cyclic adenosine 5'-monophosphate. However, in rat myometrium it was found that the relaxation resulting from activation of \$\beta_2\$-adrenergic receptors was mediated through cyclic adenosine 5'-monophosphate-dependent and cyclic adenosine 5'-monophosphate-independent mechanisms.34 Still, the relaxant effect of β2adrenergic receptor agonists can be attributed partly to the intracellular actions of cyclic adenosine 5'-monophosphate, and in human myometrium a direct correlation between the myometrial level of cyclic adenosine 5'-monophosphate and the relaxant effects of β2adrenergic receptor agonist has been demonstrated.7 Our results support this view, because both terbutaline and dibutyryl cAMP abolished the spontaneous contractions of the myometrial strips.

It has been proposed that the increased level of cyclic adenosine 5'-monophosphate caused by the β2-adrenergic receptor agonists stimulate active sodium-potassium transport,12-14, 16, 17 leading either to increased Ca++ extrusion by the Na+-Ca++ exchange mechanism8 or to decreased Ca++ entry through voltage-operated Ca++ channels because of the hyperpolarization of the cell membrane.17 Our results obtained with human myometrium, however, strongly argue against this view.

Table III. Effects of insulin, forskolin, and dibutyryl cAMP on 86Rb uptake in human pregnant myometrial strips

	Total ⁸⁶ Rb uptake (nmol/gm wet wt/min)
No additions	$226 \pm 12 (n = 12)$
Insulin (100 mU/ml)	$209 \pm 14 (n = 8)$
Forskolin (10 µmol/L)	$203 \pm 18 (n = 8)$
Dibutyryl cAMP (1 mmol/L)	$229 \pm 17 \ (n = 8)$

Values are mean ± SE with number of observations in parentheses. Strips weighing around 20 mg were prepared from isthmic region of the uterus (one subject). 86Rb uptake was measured with 10 to 20 minutes of incubation followed by washout four times for 15 minutes each at 0° C as described in legend to Fig. 3.

Ouabain and K+-free solution increased myometrial activity and tension presumably because of depolarization of the strips after inhibition of the sodium-potassium pump.36 In spite of this inhibition or blockade, both dibutyryl cAMP and terbutaline were able to abolish the contractile responses. Furthermore, both failed to stimulate the ouabain-suppressible 86Rb and 42K uptake in isolated myometrial strips.

None of the agents that are known to stimulate active sodium-potassium transport in skeletal muscle (catecholamines, insulin, dibutyryl cAMP) had any detectable effect on the ouabain-suppressible 86Rb or 42K uptake in the human myometrium. However, when the myometrial strips were loaded with Na+ and exposed to high K+, a fivefold stimulation of the active K+ uptake was observed. These results are in good agreement with those of Sanbourn,21 who found that momensin (which increases intracellular Na+) but not isoproterenol could stimulate 86Rb uptake in cultured rat myometrial cells. On the basis of our previous data on the total concentration of sodium-potassium pumps in the human myometrium (72 pmol/gm wet weight²⁹), an estimated maximum transport rate of the sodium-potassium pump of 8900 K+ ions per minute at 30° C,30 and the transport rates measured here, it could be calculated that the sodium-potassium pump in the Na+loaded strips reached around 80% of its maximum rate $(525 \times 100/0.072 \times 8900 = 82\%)$. However, under basal conditions the pumps are functioning at only 15% to 20% of the maximum transport rate. The variation observed in the measurements of 86Rb and 42K uptake is probably caused by interindividual differences in the concentration of sodium-potassium pumps, intracellular Na⁺, or both.

For isolated rat myometrium it was suggested that the β2-adrenergic receptor agonist-induced increase in cyclic adenosine 5'-monophosphate was responsible for the observed hyperpolarization of the cell membrane, and this was proposed to occur through increased K+

conductance.33 These authors further demonstrated that the hyperpolarization of the cell membrane was absent in Ca++-free medium and suggested that part of the hyperpolarization might be due to a stimulation of active Ca⁺⁺ efflux by cAMP. This hypothesis was supported by the results of Fortier et al.,37 who demonstrated that isoproterenol increased ¹⁵Ca⁺⁺ efflux in rat myometrial cell culture and that this effect was mediated by cAMP. Our results do not allow for any conclusion as to whether this is the mechanism of action of terbutaline and cAMP in the intact human myometrium as well. However, both terbutaline and Mg++ failed to increase the fractional loss of 42K from the myometrial strips, indicating that mechanisms other than increased K+ conductance are involved in the observed hyperpolarization of the cell membrane.38

Previous studies on isolated human nonpregnant myometrium²⁷ have tested only inhibitory effects of the Mg⁺⁺ at concentrations exceedingly higher (12 to 24 mmol/L) than therapeutic levels. Our results showed that Mg⁺⁺, also at concentrations within the therapeutic range of 2 to 4 mmol/L,³⁸ completely abolished the spontaneous contractions of the myometrial strips from pregnant women. Furthermore, Mg⁺⁺ abolished the contractions induced by ouabain and K⁺-free buffer and failed to stimulate ⁸⁶Rb and ⁴²K uptake in the myometrial strips. These data therefore suggest that the relaxant effects of Mg⁺⁺ cannot be attributed to increased sodium-potassium-adenosine triphosphatase activity.

Our study does not allow for differentiation between the mechanisms of relaxation of terbutaline and Mg++. There is no evidence, however, that the relaxant effects of Mg++ on smooth muscle should be mediated by an increase in intracellular cAMP. On the contrary, Sjögren and Edvinsson²⁴ found in cat vascular preparations that Mg++ interfered with Ca++ release from intracellular depots without involvement of cAMP. There is evidence that Mg++ also antagonizes the effects of Ca++ at other sites.39 Thus in human uteroplacental vasculature Mg++ was found to inhibit the responses to extracellular Ca++, probably by interfering with Ca++ influx through voltage-operated Ca++ channels.25, 26 In addition, Mg++ inhibited both resting and K+-stimulated 45Ca influx in isolated human nonpregnant myometrial strips.27

In summary, the results of this study show that the relaxant effects of Mg⁺⁺ and terbutaline in the human pregnant myometrium persist in the absence of K⁺ or in the presence of ouabain, indicating that these effects are not due to stimulation of the sodium-potassium pump. This conclusion was further confirmed by measurements of sodium-potassium pump-mediated K⁺ uptake in the same preparations. Other possible mechanisms for the relaxant properties of Mg⁺⁺ and terbutaline are currently being investigated.

We thank Ms. Kirsten Aggerholm and Ms. Ebba de Neergaard for skilled technical assistance.

Fungal morphology after treatment with itraconazole as a single oral dose in experimental vaginal candidosis in rats

Tine M. Jansen, DVM, Marie-Anne A. Van de Ven, Marcel J. Borgers, PhD, a Frank C. Odds, PhD, and Jan M.P. Van Cutsemb

Beerse, Belgium

The therapeutic effect of a single, oral dose of itraconazole was studied in rats inoculated intravaginally with Candida albicans and in which an established vaginal infection was present. We used light microscopy, transmission and scanning electron microscopy to document the structural alterations in the 3 days after treatment. The most important observations include the speed (within 24 hours) with which itraconazole inhibits the further penetration of the fungus into the vaginal squamous epithelium, the ability of the drug to reach and structurally alter intracellularly located fungal elements, and the prolonged drug effect of a single dose leading to complete eradication of the fungus from the vagina within 3 days. (AM J OBSTET GYNECOL 1991;165:1552-7.)

Key words: Itraconazole, single oral dose; vaginal candidosis, rat; light microscopy, transmission electron microscopy, scanning electron miscroscopy

Itraconazole is an orally active triazole antifungal. It has performed well in the treatment of experimental vaginal candidosis in animals1-5 and in clinical trials with vaginal candidosis. 6-8 In both instances the total antifungal dose administered has proved to be more important than the length of therapy (usually 1, 2, or 3 days).3,7 This observation has led to shorter treatment courses with higher antifungal doses and finally to 1day therapies, resulting in superior patient compliance compared with the long courses of oral or topical antifungals.9 In experimental and clinical studies cure rates mostly have been based on both clinical cure and culture of vaginal samples. Although these methods are valuable to assess therapeutic results, a clear picture of the interaction of the antifungal drug with the fungus in situ cannot be obtained. In this respect ultrastructural studies of the morphologic features and distribution of the fungus within the vaginal epithelial layers may offer important, complementary information on the drug-fungus interaction, especially in the early phase after treatment. To study the ability of itraconazole, given as a single oral dose, to induce ultrastructural fungal damage, and finally to eradicate Candida albicans from the vagina, we used light microscopy and transmission and scanning electron microscopy in rat vaginal candidosis, which is a well-established model for the evaluation of antifungals1, 8-5, 10-12 and which

shares important features with those described for human vaginal infections.9

Material and methods

Female Wistar rats weighing 100 gm underwent oophorectomy and hysterectomy. Eighteen days later, 100 µg of estradiol undecylate in sesame oil was injected subcutaneously into each rat. The induced pseudoestrus was checked by microscopic examinations of vaginal smears. Only animals in pseudoestrus were inoculated intravaginally with 8 × 10⁵ blastospores of C. albicans (strain ATCC 44858). Curative treatment with placebo or with itraconazole (10 or 20 mg/kg) was given as a single dose by gavage on the fourth day after inoculation. Each treatment group consisted of six animals. Two control rats, untreated but infected, were killed on the fourth day after infection, and two rats of each treatment group were killed at 24, 48, and at 72 hours after treatment. The vagina was removed and fixed as a unit in 3% glutaraldehyde buffered to pH 7.4 with 0.1 mol/L sodium cacodylate at room temperature for 48 hours. The vagina was then divided into different parts (separate pieces for light and transmission electron microscopy and for scanning electron microscopy) and washed in the same buffer to which 0.22 mol/L sucrose was added. The specimens were then postfixed for 1 hour in 2% osmium tetroxide buffered to pH 7.4 with 0.05 mol/L veronal acetate. After a brief wash in the buffer, they were impregnated with 0.5% uranium acetate in veronal acetate buffer (pH 5.2) for 40 minutes and subsequently rinsed in the same buffer. After dehydration in a graded series of ethanol, they were routinely embedded in epon. Semithin sections were made for light microscopic exami-

was reached. They were dried at the critical point, sputtered with a layer of gold, and examined in a Philips PSEM 500 microscope.

The experiments were conducted in accordance with the principles and standards as set forth in the Guide for the Care and Use of Laboratory Animals, the Johnson & Johnson Policy on the Humane Care and Use of Experimental Animals, and the International Guiding Principles for Biomedical Research Involving Animals.

Results

Light, scanning electron, and transmission electron microscopy of the vaginal wall revealed that 4 days after inoculation of yeasts, the vaginal epithelium still presented a picture of pseudoestrus, characterized by marked hyperkeratosis and pronounced exfoliation of the horny layer. The entire squamous cell layer was colonized by fungal elements, both yeast cells and filamentous forms, but the fungi did not penetrate deeper than the keratinized epithelium. Transmission and scanning electron microscopy confirmed the presence of C. albicans within the cytoplasm of epithelial squamous cells, and interspersed between epithelial cells, fungal elements together with bacteria were abundant. Inflammatory cells were not present. Transmission electron microscopy of cross sections of fungal elements, in most instances, revealed a normal ultrastructure and only occasional cells presented a degenerated cytoplasm. Thus, at the moment oral therapy

was given, an established vaginal fungal infection was present. One day later the infection had further increased in severity in the placebo-treated animals, as evidenced in vaginal cross sections by the increased number of fungal elements on light, transmission electron, and scanning electron microscopy, but penetration into the nucleated epithelial cell layers did not take place (Fig. 1, a). However, in animals treated with itraconazole (10 and 20 mg/kg), a yeast- and myceliumfree zone of squamous epithelium adjacent to the nucleated cell layers was found (Fig. 1, b and c). The fungus-free zone comprised between 10 and 20 squamous cell layers. On transmission electron microscopy, fungal elements in all locations from the lumen to the deepest site within the horny cell layers showed cell wall alterations typical of azole treatment (Fig. 2, a and b, and Fig. 3, a and b). These changes, which also were noted in fungal elements located intracellularly, consist of an irregularly thickened cell wall containing phospholipid-like vesicles. Such vesicles also accumulate between the plasma membrane and the cell wall. Necrosis of the intracellular contents, together with a decreased number of fungal elements, was a further difference noted on comparison with the placebo-treated animals, although these were less objectively evident. No clear difference was seen day 1 or 2 after treatment between animals treated with placebo or itraconazole (10 or 20 mg/kg) (Fig. 1, b, c, e, and f).

Three days after treatment, however, a substantial

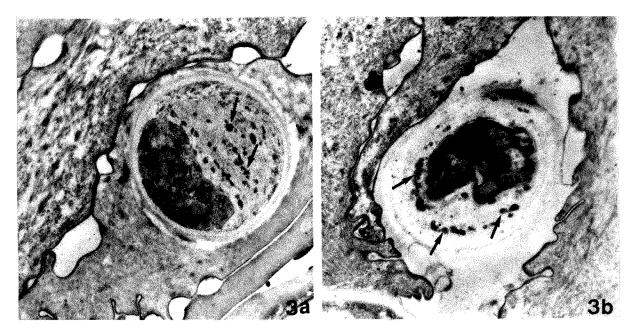

Fig. 3. Transmission electron microscopy of C. albicans in squamous vaginal epithelium of itraconazole (10 mg/kg)-treated rats, 24 hours after treatment, illustrating early changes, typical of azole treatment: electron-dense inclusions (arrows) in abnormally thickened cell wall. Changes are seen in intracellularly (a) and in extracellularly (b) located fungal elements. (a, Original magnification \times 18,600. **b,** Original magnification \times 16,200.)

difference existed between the rats dosed with 10 and 20 mg/kg. Where the infection was still present in the upper squamous cell layers of the 10 mg/kg treated animals, with numerous necrotic fungal elements demonstrating the cell wall changes described above, the 20 mg/kg dose had resulted in a complete eradication of the fungus from the vaginal epithelium and the intraluminal cellular debris (Fig. 1, g to i, and Fig. 4, a to c).

A bacterial flora was present in all vaginal specimens without exception and on no occasion seemed to be influenced by the therapy. In some specimens neutrophils, situated in the upper epithelial layers and in the vaginal lumen, were seen to engulf bacteria avidly, but phagocytosis of fungal elements was not seen in any of the treatment groups.

Comment

The findings of this study indicate that, in a wellestablished vaginal C. albicans infection in rats, a single dose of itraconazole is able to induce ultrastructural cell wall changes in fungal elements located within the vaginal epithelium, even in those that are located intracellularly, and this is within 24 hours after a single-dose therapy. The changes seen, inclusions in the cell wall and between the cell wall and the plasma membrane, have been reported previously for itraconazole and other azole antifungals in vitro and in vivo after topical and oral treatment and may be considered a consequence of azole treatment because they never occur in

spontaneously degenerating cells.2.13-15 They are to be considered as the morphologic counterpart of the inhibition of ergosterol biosynthesis in the fungal cell, a mechanism of action common to all azole antifungals. 16-18 The appearance of cell wall alterations parallels the observation that in the 24 hours after therapy the fungus is no longer able to invade the newly formed hyperkeratotic cell layers. This observation is consistent with the data on the interaction of itraconazole with C. albicans in vitro, 2, 19, 20 which demonstrate that the drug is able to inhibit the transformation of the yeast form into the filamentous form at concentrations that can be reached in plasma and tissue in man and animals after oral administration.21.22 The flexible interconversion between blastospores and filamentous forms and vice versa has been implicated as an important factor and maybe even as the determining factor in the pathogenicity of C. albicans in natural infections and is considered to be more important than the role played by either form alone.9 Intracellular hyphal elements have been described by others,23-25 and it is possible that they provide a means of escaping host defense systems. 15 Two possible explanations for the relapse sometimes seen after antifungal therapy have been either that antifungal drugs with poor lipophilicity and limited tissue penetration do not reach these intracellular fungal cells or that the latter are not metabolically active and therefore are not affected by the antifungal action of the drug. In this respect the observation that intracellular fungal elements do seem to be metabolically active and 1556 Jansen et al.

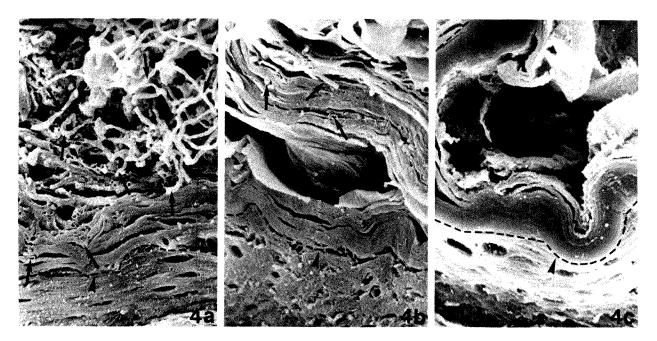

Fig. 4. Scanning electron microscopy of rat vaginal epithelium at 72 hours after single oral treatment, illustrating extensive colonization of squamous epithelium by *C. albicans* hyphae after placebo treatment (a). Treatment with 10 mg/kg itraconazole has inhibited further hyphal invasion of newly formed squamous cell layers (b), whereas 20 mg/kg itraconazole treatment has eradicated yeast from vaginal wall (c). *Arrowheads* point at *dotted line*, separating squamous from nucleated epithelial cell layers, whereas *arrows* point at *C. albicans* hyphae. (Original magnification ×500.)

that they are within reach of the action of itraconazole may well be an explanation for the unusually low relapse rates observed after use of this compound in the treatment of vaginal candidosis. The typical alterations of fungal morphologic features within 24 hours of therapy illustrate that the fast action of itraconazole is a direct result of a drug-*Candida* interaction and not the result of an indirect effect of the drug on the turnover of the vaginal epithelium, an action that has been reported to contribute to the overall therapeutic effect of ketoconazole in the same animal model. This observation further illustrates the importance of evaluating the effect of antifungal drugs on the host-pathogen interaction in situ.

Transverse sections of the vaginal squamous epithelium made in the 3 days after treatment clearly illustrate the depth of the infection and the effect of a fungistatic treatment on it. At each moment the aspect of the infected vaginal epithelium is determined by the speed with which the fungus penetrates the newly formed squamous cell layers and the speed with which these new cell layers are formed. Both itraconazole doses were equally effective in reaching and inhibiting the most deeply located fungal elements, but complete eradication of yeasts from the vagina within 3 days was obtained only with the 20 mg/kg dose. This observation is in agreement with that of Sobel and Muller,³ who reported that complete mycologic cure could be ob-

tained with a single dose of 25 mg/kg in the same animal model. The same efficacy could be obtained by one of us27 with a 3-day regimen of itraconazole 2.5 mg/kg/day, which illustrates the importance of the dose administered in relation to the duration of therapy, a relation that also has been confirmed in patients by Cauwenbergh.7 The prolonged action of itraconazole after a single dose can be explained by the drug's lipophilic properties, which guarantee sustained tissue levels for several days at the infection site. Determination of drug concentrations in human vaginal tissue after a single oral dose of 200 mg and in rat vaginal fluid after a single oral dose of 10 mg/kg has confirmed that inhibitory concentrations can be found for at least 3 days.^{3, 5, 28} The fact that these levels have to be high enough for a critical period of time to obtain complete eradication is well illustrated in this study and agrees with the observations of Sobel and Muller³ that suboptimal single doses do not result in mycologic cure.

In healthy rats polymorphonuclear leukocytes have been noticed in the vaginal lumen and in the upper epithelial layers during late metestrus and particularly during diestrus.²⁰ When *C. albicans* blastospores were introduced into the vagina of rats and mice during diestrus, phagocytosis of spores was observed.^{30, 31} All attempts however to induce an infection of the squamous epithelium at this stage of the estrus cycle have proved to be unsuccessful. In rats and mice with vaginal

candidosis artificially induced during pseudoestrus and in spontaneous vaginal *Candida* infections in women, the presence of polymorphonuclear leukocytes, although not consistently, was noticed. ³⁰⁻³² Ingestion of *Candida* by these polymorphonuclear leukocytes, however, was not reported.

Although phagocytic cells are believed to be major components of the host defense against deep-seated *Candida* infections, clinical and experimental observations reported so far support the current opinion that phagocytic cells are less important in the defense against *Candida* in superficial sites, such as the mouth, the skin, and the vagina.³³ In these sites defense probably depends critically on a multiplicity of host defense factors, as it does in any part of the body.

Role of endogenous atrial natriuretic factor in the regulation of fetal cardiovascular and renal function

Cecilia Y. Cheung, PhD

La Jolla, California

The purpose of the present study was to determine whether endogenous atrial natriuretic factor participates in the maintenance of normal vascular pressure and renal function in ovine fetuses at 128 to 130 days' gestation. Circulating atrial natriuretic factor in the fetus was immunoneutralized by an intravenous bolus injection of an atrial natriuretic factor antiserum at a dilution of 1:2000 (low dose, n = 7) or 1:400 (high dose, n=6). In the high-dose group, plasma atrial natriuretic factor concentration was significantly reduced by 65 \pm 14 pg/ml from basal levels of 165 \pm 12 pg/ml within 10 minutes and remained reduced for the 90-minute period after the injection. Fetal arterial pressure acutely and transiently decreaased, but at 50 minutes arterial pressure increased and was elevated for the remainder of the experiment. Urine flow and urinary excretion rates of sodium, potassium, and chloride were reduced within 10 minutes after the injection. Urine flow rate was suppressed for as long as plasma atrial natriuretic factor concentrations were reduced. Fetuses in the low-dose and control groups showed no significant change in cardiovascular or renal function. In response to atrial natriuretic factor antiserum injection, plasma angiotensin II concentrations were increased, whereas plasma arginine vasopressin concentrations were unchanged. These results suggest that endogenous atrial natriuretic factor is involved in the maintenance of arterial pressure and urinary excretion in the ovine fetus. (AM J OBSTET GYNECOL 1991;165:1558-67.)

Key words: Atrial natriuretic factor, fetus, antiserum, urine flow, vascular pressure, angiotensin II, arginine vasopressin

In the mammalian fetus, atrial natriuretic factor (ANF) has been implicated in the regulation of blood pressure and fluid volume. Administration of ANF into the fetal circulation decreases arterial pressure and blood volume, while having little effect on venous pressure or heart rate. The renal effects of ANF are largely similar to those in the adult, in that it increases fetal urine flow rate, glomerular filtration rate, and enhances urinary electrolyte excretions.2.3 However, these effects occur only at high ANF concentrations and appear to be gestational-age dependent.4 Contrary to that in the adult, the interaction of ANF with other endocrine systems in the fetus is minimal, except at supraphysiologic concentrations when arginine vasopressin and plasma renin activities are increased in response to ANF infusion. 5,4 These observations suggest that ANF may not be playing a significant role in the regulation of vascular pressures or fluid dynamics in the fetus. However, ANF concentrations in the fetal circulation are higher than

those in the adult,4-6 and physiologic manipulations of the fetal cardiovascular system can significantly alter fetal plasma ANF concentrations. For example, expansion of the fetal vascular volume7 or fetal hyperosmolality8 increases plasma ANF levels, whereas reduction in fetal blood volume decreases circulating ANF concentrations.9 Furthermore, fetal hypoxia elevates plasma ANF levels.10 Therefore, to document in the fetus the contribution of endogenous ANF to the physiologic maintenance of blood pressures, urine flow, and electrolyte excretion and its interaction with other hormones, this study was undertaken to investigate the cardiovascular, renal, and endocrine effects of blockade of endogenous ANF action. Since a physiologic antagonist to ANF is currently not available, an antiserum was used for these studies, to immunoneutralize endogenous ANF in the fetal circulation.

Methods

Eleven pregnant sheep with singleton fetuses were used for these studies. The experimental protocol was approved by the University committee on animal research. We followed the guidelines of the University and the National Institutes of Health for the care and use of these animals. With the animals under gas inhalation anesthesia (1% to 2% halothane in oxygen), chronic vascular catheters were implanted in the fetal descending aorta and inferior vena cava at the level of

the diaphragm. Additional catheters were placed in the urinary bladder and in the amniotic cavity using procedures previously described.¹¹ Prophylactic antibiotics were administered to the ewe and into the amniotic fluid for the first 5 postsurgical days.

Experiments were carried out at least 5 days after surgery. The gestational ages of the fetuses at the time of experimentation were 128 to 139 days (term 145 to 150 days). Four fetuses were experimented on once, and seven were experimented on twice, with 48 hours allowed for recovery between experiments. During the experiment, arterial pressure, venous pressure, heart rate, amniotic fluid pressure, and urine flow rate were continuously monitored on a polygraph recorder, and data were stored with an on-line computer.12 The fetal vascular pressures were continuously corrected with the on-line computer, with amniotic fluid pressure used as the zero pressure reference. For data analysis of vascular pressures, heart rate, and urine flow rate. 2-minute averages of the on-line data were taken and stored in a file for statistical evaluation.

After a 30-minute control period, an ANF antiserum was injected intravenously as a bolus into the fetal circulation. This was followed by a 90-minute observation period. The antiserum was generated against the carboxyl terminal of human ANF₁₋₂₈ (Peninsula Laboratories, Belmont, Calif.). We have successfully used this antiserum for the measurement of ANF concentrations in the pregnant sheep and their fetuses.5 The antiserum recognizes ovine ANF and, when used at a dilution of 1:25,000 for radioimmunoassay (RIA), it has a sensitivity of 3 pg of human ANF₁₋₂₈. One group of fetuses (low dose, n = 7) was given the antiserum at a dilution of 1:2000 in 2 ml of 1% normal rabbit serum diluted in phosphate-buffered saline solution. A second group of fetuses (high dose, n = 6) was given the antiserum at a dilution of 1:400 in 2 ml of 1% normal rabbit serum. A separate group of fetuses were used as controls (n = 5) and were given 2 ml of 1% normal rabbit serum.

Samples of fetal blood at 3.5 ml each and urine at 1 ml each were taken at 10 minutes after the start of the control period and at 15-minute intervals thereafter. The fetal blood removed by blood sampling was replaced by an equal volume of heparinized maternal blood. In the blood samples, blood gases (IL 1302 blood gas analyzer, Instrumentation Laboratory), hematocrit (in triplicate), plasma protein concentration (American Optical, TS meter), and plasma ANF, arginine vasopressin, and angiotensin II concentrations were measured. In the urine samples, osmolality (Advanced Diagnostic Osmometer 3D2) and electrolyte concentrations (Nova 5 + 5 electrolyte analyzer) were measured. Plasma ANF concentrations were determined by RIA with procedures previously described⁵ with the follow-

ing exception: The ANF concentration in the samples was measured by a direct assay without the extraction step. This was necessary because the ANF antibody, when injected into the fetus, became bound to the hormone, thus reducing the concentration of free ANF in the circulation. Extraction of these plasma samples with the Sep-Pak procedure would dissociate the antibody from the ANF, thereby freeing the ANF for subsequent RIA. This would result in measurement of total ANF in the plasma instead of free ANF left unbound by the injected antiserum. By using the plasma directly for RIA without extraction, the concentration of free ANF in the plasma not bound by the injected antiserum could be obtained. In a previous study in the rat a similar direct assay procedure was used to determine the level of free ANF in the circulation after antibody administration.13 We have validated this method by the addition of the antiserum to a pool of fetal plasma before subjecting to direct RIA and obtained antiserum dilution-dependent reductions of ANF concentration in the plasma. Furthermore, when the fetal plasma pool (without antiserum addition) was measured by the direct method, as well as after extraction, the mean value obtained with the direct method was 9% greater than with the extracted method. There were no statistically significant differences between the values obtained by the two methods. Plasma concentrations of arginine vasopressin and angiotensin II were determined by RIA after extraction, as has been reported previously.¹⁴

The data are presented as the mean \pm SE. The change in blood volume at a given time was calculated as a percent of control using the mean hematocrit values.15 To explore changes with time in a given variable, a two-factor analysis of variance was used, with time and animal being the two factors. If a significant F value was obtained, individual group means were compared with Fisher's least-significant-difference test. In some instances, when the intraanimal variability was large, a nonparametric analysis of variance was used. (Friedman's nonparametric test, which was the equivalent of a two-factor analysis of variance, with time and animal being the two factors, calculated a value for χ^2 .) Data were considered statistically significant if p < 0.05. Urinary excretion rate of each of the electrolytes—sodium, potassium, and chloride—was calculated as the product of urine flow rate and urinary concentration of the electrolyte.

Resuits

Basal conditions. For the fetuses in the control, low-dose, and high-dose groups, the gestational age at the time of experimentation and the control values during basal conditions are given in Table 1. There was no significant difference in any of these variables among the three groups of animals studied.

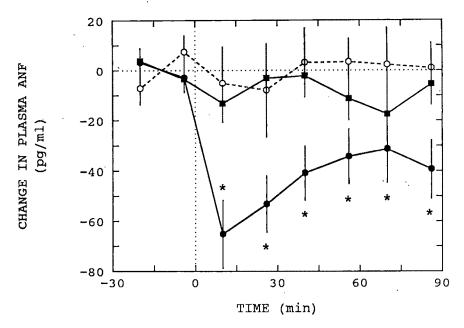

Fig. 1. Changes in fetal plasma ANF concentration (mean \pm SE) after ANF antiserum injection at 30 minutes in low-dose (solid squares), high-dose (solid circles), and control (open circles) groups. Asterisk, p < 0.05 compared with control values during first 30 minutes of experiment. Dotted line, Time of ANF antiserum injection.

Plasma ANF (pg/ml)	165 ± 24	115 ± 20	165 ± 12
Plasma arginine vasopressin (pg/ml)	8.12 ± 2.12	4.03 ± 0.64	8.13 ± 5.20
Plasma angiotensin II (pg/ml)	32.5 ± 6.4	25.7 ± 5.4	30.3 ± 5.8

After the 30-minute control period, the ANF antiserum was injected into two groups of fetuses. The low-dose group received the antiserum at 1:2000 dilution, and the high-dose group received the antiserum at 1:400 dilution. The control group was given an injection of the diluent.

Low-dose group. In the low-dose group administration of the ANF antiserum lowered fetal plasma ANF concentration from control levels of 115 ± 20 pg/ml by 13 ± 7 pg/ml at 10 minutes (Fig. 1). However this decrease was not statistically significant (F = 1.19,

p = 0.33; two-way analysis of variance). Fetal arterial pressure decreased sharply by 1.6 ± 0.4 mm Hg (F = 2.02, p = 0.06), returned to basal levels by 10 minutes after this low-dose antiserum injection, and was unchanged for the remainder of the experiment. Fetal heart rate increased transiently by 10 ± 4 beats/min (F = 1.98, p = 0.07) and returned to basal levels within 10 minutes after the injection. Venous pressure did not change significantly at any time after the antiserum administration (F = 1.00, p = 0.42). There was a small increase in fetal blood volume of

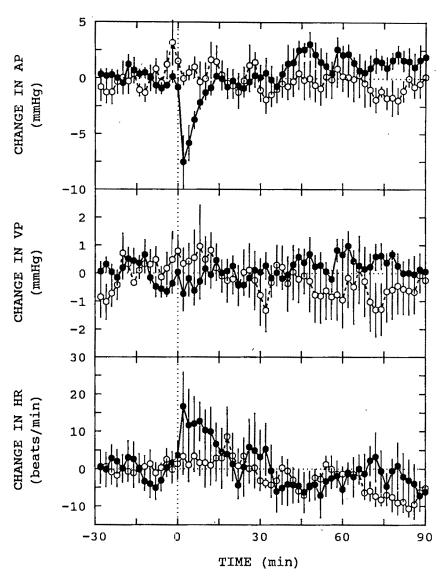

Fig. 2. Changes in fetal arterial pressure (AP), venous pressure (VP), and heart rate (HR) (mean \pm SE) after ANF antiserum injection at 30 minutes in high-dose (solid circles) and control (open circles) groups. See text for statistical analysis. Dotted line, Time of ANF antiserum injection.

 $1.8\% \pm 0.7\%$ at 10 minutes after the injection, but the change was not statistically significant (F = 1.73, p = 0.14). By 40 minutes, blood volume had returned toward baseline. Plasma protein concentrations did not change immediately after the low-dose antiserum injection but was elevated at 40 minutes after the injection (F = 3.81, p < 0.01). Thereafter, plasma protein remained elevated until the end of the experiment. Fetal arterial blood gases and pH did not change significantly throughout the experiment. Similarly, fetal urine flow rate; urine osmolality; and urinary sodium, potassium, and chloride excretion rates did not change in response to the low-dose antiserum treatment.

High-dose group. In the high-dose group injection of the ANF antiserum significantly reduced fetal

plasma ANF concentration (F = 6.17, p < 0.001) within 10 minutes by 65 \pm 14 pg/ml from control levels of 165 \pm 12 pg/ml (Fig. 1). Plasma ANF levels remained reduced for the duration of the experiment. Fetal arterial pressure showed significant changes after the high-dose antiserum injection (F = 4.22, p < 0.01; Fig. 2). There was an acute and transient fall in arterial pressure of 7.6 \pm 2.4 mm Hg from control, followed by a return to basal levels at 10 minutes after the injection. At 40 minutes, arterial pressure began to rise and reached a maximum increase of 3.0 \pm 1.1 mm Hg from control at 50 minutes after the injection (p < 0.05). Thereafter, arterial pressure was elevated for the remainder of the experiment. Venous pressure showed no consistent change throughout the experi-

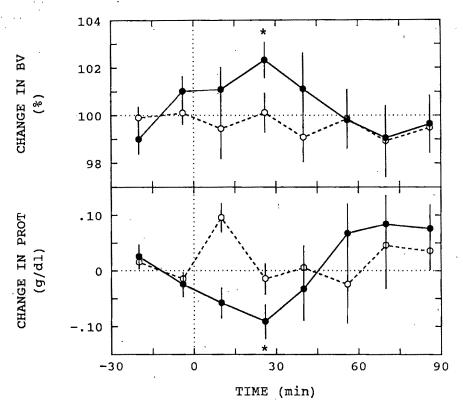

Fig. 3. Changes in fetal blood volume (BV) and protein (PROT) concentrations (mean \pm SE) after ANF antiserum injection at 30 minutes in high-dose (solid circles) and control (open circles) groups. Asterisk, p < 0.05 compared with control values during first 30 minutes. Dotted line, Time of ANF antiserum injection.

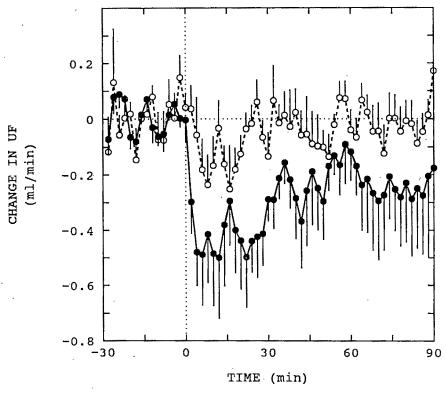

Fig. 4. Changes in fetal urine flow rate (UF, mean \pm SE) after ANF antiserum injection at 30 minutes in high-dose (solid circles) and control (open circles) groups. See text for statistical analysis. Dotted line, Time of ANF antiserum injection.

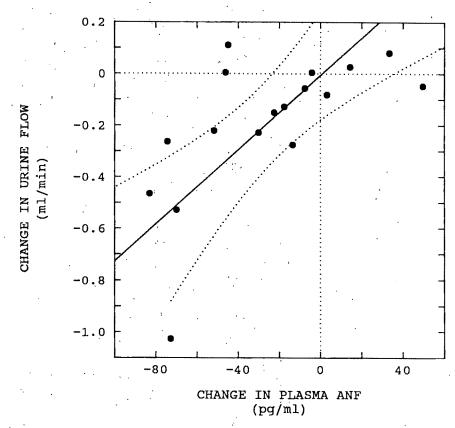

Fig. 5. Correlation between change in urine flow rate and change in plasma ANF concentrations in low-dose, high-dose, and control groups of fetuses during 30 minutes after ANF antiserum injection (r = 0.64, p < 0.01, n = 18).

ment (F = 1.05, p = 0.39; Fig. 2). The fetal heart rate changes were reciprocal to those in arterial pressure. Heart rate increased sharply by 17 ± 9 beats/min and gradually returned to basal levels by 20 minutes after the injection (F = 1.22, p = 0.30; Fig. 2). Heart rate continued to fall by a maximum of 7 ± 6 beats/min below basal levels at 50 minutes after the injection and slowly returned to control levels by the end of the experiment. Because of the variability among the animals, these changes in fetal heart rate were not statistically significant.

Fetal blood volume increased after the high-dose antiserum injection to a maximum of $2.3\% \pm 0.7\%$ above control at 25 minutes after the antiserum injection (F = 1.50, p = 0.22; Fig. 3) and returned to control levels thereafter. Concurrent with the increase in blood volume, there was a nonsignificant decrease from control in plasma protein concentrations at 25 minutes, which gradually rebounded to levels significantly above baseline at 50 minutes after the injection (F = 3.56, p < 0.01; Fig. 3). There were no consistent changes in fetal arterial blood gases and pH after ANF antiserum injection.

In response to the high-dose ANF antiserum, fetal urine flow rate was significantly suppressed within 5 minutes by 0.5 ± 0.1 ml/min from a basal rate of $0.8 \pm 0.2 \text{ ml/min}$ (F = 2.53, p < 0.05), and remained low at this level for 30 minutes. Thereafter, although urine flow increased somewhat, it remained below basal levels for the remainder of the experiment (Fig. 4). During the 30 minutes after antiserum administration, the reduction in urine flow was significantly correlated with the decrease in plasma ANF concentrations (r = 0.64, p < 0.01; Fig. 5). Urine osmolality increased by 33 ± 17 mOsm/kg from control at 25 minutes after the antiserum injection (F = 2.52, p < 0.05) but returned to baseline at 55 minutes. Urinary excretion rates of sodium, potassium, and chloride decreased significantly at 10 minutes after the injection $55\% \pm 12\%$ (Friedman's $\chi^2 = 15.2$, p < 0.01), $52\% \pm 10\%$ (Friedman's $\chi^2 = 17.0$, p < 0.01), and $54\% \pm 12\%$ (Friedman's $\chi^2 = 16.6$, p < 0.01) of control values, respectively. However, by 40 minutes after the antiserum injection, urinary electrolyte excretion rates were not different from basal levels (Fig. 6).

In fetuses of the control group, variations in cardiovascular variables during the entire experimental period were within the 95% confidence interval about the mean during the 30-minute control period. There were no significant changes in blood gases, pH, or renal function in these fetuses throughout the experimental period.

Hormone responses to ANF antiserum injection. In the low-dose and the high-dose groups, plasma angio-

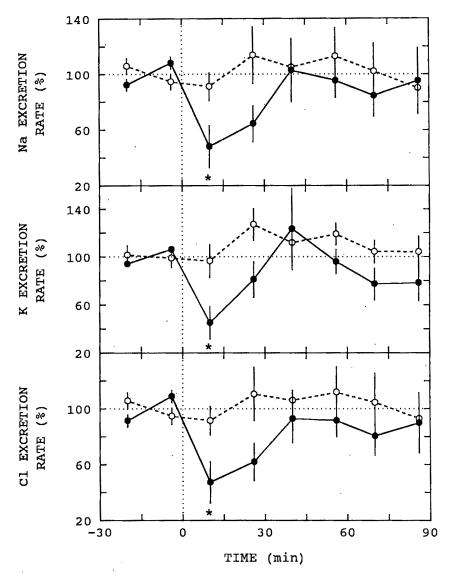

Fig. 6. Percent changes in sodium (Na), potassium (K), and chloride (Cl) excretion rates (mean \pm SE) after ANF antiserum injection at 30 minutes in high-dose (solid circles) and control (open circles) groups. Asterisk, p < 0.05 compared with control values during first 30 minutes of experiment. Dotted line, Time of ANF antiserum injection.

tensin II concentrations increased after the ANF antiserum injection (Fig. 7). The angiotensin II responses were similar in the two groups; therefore the data were combined for statistical analysis. At 10 minutes after ANF antiserum injection, angiotensin II concentrations were elevated by 22 ± 9 pg/ml from control levels of 28 ± 4 pg/ml (F = 2.55, p < 0.01). Angiotensin II concentrations returned toward basal levels by the end of the experiment.

In both the low-dose and high-dose groups, plasma arginine vasopressin concentrations during the 90-minute period after ANF antiserum administration were not significantly altered from the levels in the control period (Fig. 7).

Comment

To determine the role of endogenous ANF in the maintenance of fetal cardiovascular and renal functions, ovine fetuses were studied after suppression of endogenous ANF. Because of the unavailability of an effective antagonist for ANF, blockade was accomplished by immunoneutralization of endogenous ANF with a specific antiserum. Using similar techniques of immunoneutralization of ANF in adult rats, other investigators have reported that endogenous ANF is consistently involved in the maintenance of urinary output and renal sodium excretion. ^{13, 16, 17} The effect of ANF on arterial pressure was variable in that ANF antiserum treatment was shown to have either no effect. ¹³ or sig-

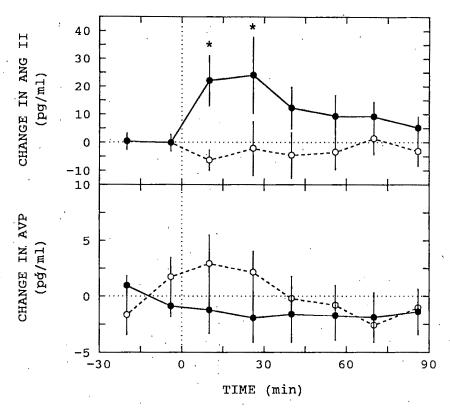

Fig. 7. Changes in plasma angiotensin II (ANG II) and arginine vasopressin (AVP) concentrations (mean \pm SE) after ANF antiserum injection at 30 minutes in control fetuses (open circles, n=5) and fetuses given both low-dose and high-dose-ANF antiserum (solid circles, n=13). Asterisk, p < 0.05 compared with control values during first 30 minutes. Dotted line, Time of ANF antiserum injection.

nificantly increased arterial pressure.¹⁷ In this study, when the antiserum was administered in sufficient quantities as a bolus to the ovine fetus, plasma ANF concentration was significantly and consistently reduced for at least 90 minutes. This reduction in circulating ANF levels resulted in significant alterations in fetal arterial pressure, blood volume, and renal excretion of fluid and electrolytes. These findings are consistent with the role of ANF as a physiologic regulator of vascular pressure and fluid balance in the fetus under basal conditions.

In the fetus, plasma ANF concentration is normally greater than that in the adult, 46 and the endogenous release rate of ANF is high at 13 ng/min/kg. The present study demonstrated that a high concentration of ANF antiserum was required to reduce plasma ANF to 58% of basal levels. The use of a lower dose (a fivefold higher dilution) of ANF antiserum reduced plasma concentrations to only 88% of basal levels. In this low-dose group, although ANF levels were below control levels after antiserum injection, at no time was this decrease significant. These observations are consistent with the high production rate of ANF in the fetus.

The initial arterial pressure response of the fetus to the high-dose antiserum injection was an abrupt but transient fall in arterial pressure. This fall in pressure was also seen in the low-dose group, although the decrease was much smaller in magnitude than in the highdose group. This decrease, however, was not detected in the control group of fetuses given 1% normal rabbit serum. This acute hypotension was an unexpected finding. It appeared to be related to the presence of the antiserum itself and might not be the result of the blockade of ANF action. Instead, it could be a nonspecific effect of the rabbit antiserum, such as the induction of complement activation by the antibody leading to histamine release, that caused a vasodilation and reduction in arterial pressure. The abrupt fall in arterial pressure would likely affect the fetal cardiovascular system. In studies where fetal hypotension was induced by nitroprusside, arterial pressure fell and remained reduced as long as nitroprusside was infused.18 In addition, all cardiovascular variables returned to normal within 10 minutes after termination of the nitroprusside infusion. In this study the arterial hypotension was transient; arterial pressure returned to baseline within 10 minutes and then increased to levels above basal conditions. This was contrary to a maintained hypotensive response such as that induced by nitroprusside. The transient nature in the fall in arterial pressure and the quick recovery suggested that it was not caused by the blockade of ANF action, because plasma ANF levels were reduced for a prolonged period. In previous studies of the adult rat^{18, 16, 17} a transient hypotensive effect after ANF antiserum administration was not reported. However, in those studies arterial pressure was measured at 15- to 30-minute intervals rather than the continuous recording and display (Fig. 2) used in this study. Thus it is unclear whether the transient fall in arterial pressure was missed by the previous investigators.

The reduction of plasma ANF concentrations to levels below normal in the fetus produced a delayed but sustained rise in fetal arterial pressure of $6.2\% \pm 2.2\%$ that was maintained for as long as plasma ANF concentration was suppressed. These findings are consistent with our previous report that infusion of exogenous ANF into the ovine fetus lowered arterial pressure.3 An increase in arterial pressure after ANF antiserum treatment has also been reported in the adult rat.17 The fetal heart rate responses to the ANF antiserum were reciprocal to those of arterial pressure, indicating a baroreceptor mechanism in the maintenance of fetal heart rate. A direct effect of ANF withdrawal on the fetal heart was not apparent. Fetal venous pressure was not consistently affected by the presence of the ANF antiserum. These results support the concept that, in the fetus, ANF normally participates in the maintenance of arterial pressure but not venous pressure or heart rate.

It has been demonstrated in the adult19 and the fetus3 that administration of ANF increases hematocrit, suggesting a reduction in blood volume. In the ovine fetus this decrease in blood volume is associated with a transient increase in plasma protein concentration. In this study blockade of endogenous ANF in the fetus resulted in a rise in blood volume (although not significant), accompanied by a fall in plasma protein concentration. These observations are consistent with a modulatory role of ANF in the transfer of proteins and fluids across the capillary in the fetus. However, urine flow rate was dramatically reduced at this time; therefore the retention of fluids by the fetal kidney might have contributed to the increase in blood volume. Although the acute, transient fall in arterial pressure might have allowed movement of fluid from the interstitium into the vascular compartment, causing an increase in blood volume, this appeared to be unlikely. This was because blood volume was not elevated until arterial pressure had returned to basal conditions. The elevation in blood volume was not maintained, even though plasma ANF concentrations remained suppressed. This might be partly due to the subsequent increase in arterial pressure in these fetuses.

The fetal renal response to ANF antiserum was much more pronounced than the cardiovascular effects. This was because of the observation that, after blockade of endogenous ANF, fetal urine flow rate was abruptly reduced to $41.4\% \pm 9.6\%$ of control values. The sharp, transient decrease in arterial pressure in response to ANF antiserum injection could have augmented the fall in urine flow rate, because it has been reported that in the ovine fetus hypotension induced by nitroprusside was accompanied by a fall in urine flow rate and urinary sodium excretion.20 However, in those studies the fall in urine flow was terminated as the hypotension was reversed. In the present study, the suppression of urine flow rate was prolonged even though the hypotension subsided. Thus it was unlikely that the long-term reduction in urine flow was the result of the short-term decrease in arterial pressure. Furthermore, plasma arginine vasopressin levels did not change during the entire experiment, thus eliminating its possible involvement in reducing urine flow. The fall in urine flow was most likely the result of the withdrawal of ANF, because a significant relationship existed between the fall in plasma ANF concentrations and the reduction in urine flow. This implies that by blocking the renal effects of ANF, urine flow was no longer maintained. Thus, under physiologic conditions, normal fetal urine flow appears to be maintained by circulating ANF levels. In support of this concept is the fact that plasma ANF concentration in the fetus is greater than in the adult, and urine flow rate is higher in the fetus than in the adult relative to body weight.

In conjunction with the suppression of urine flow, urinary excretion rates of sodium, potassium, and chloride were reduced. This reduction in electrolyte excretion might be the consequence of the blockade of the natriuretic action of ANF. However, the large concomitant reduction in fetal urine flow rate would have contributed to the decrease in urinary electrolyte excretion rates. The diuretic action of ANF is mediated through an increase in glomerular filtration rate at the fetal kidney.2 When ANF levels were reduced, a decrease in glomerular filtration rate would result. In this study, this was manifested as a fall in urine flow rate. With the reduction in glomerular filtration rate, the filtered load through the kidney was reduced, and thus the amount of electrolytes filtered decreased. The result was a fall in urinary excretion of the electrolytes. This fall in electrolyte excretion rate might be augmented by the action of aldosterone, because plasma aldosterone concentration was found to increase in response to ANF antibody injection in the rat. 13 However, this possibility is unlikely because of the observation in the ovine fetus that aldosterone stimulated the reabsorption of sodium but increased the excretion of potassium, leading to a decrease in the sodium-potassium ratio in the urine.21 This was inconsistent with our finding, where both sodium and potassium excretion rates

were reduced. Similarly in the studies by Sasaki et al.¹⁷ and Rudd et al.,¹⁸ the urinary excretion rates of both sodium and potassium were reduced after ANF antiserum treatment. Unlike urine flow that was continuously suppressed in parallel with the reduction in plasma ANF concentration, the excretion of electrolytes returned to basal levels. This increase in electrolyte excretion could not be due to a fall in plasma arginine vasopressin concentration, because arginine vasopressin levels did not change at any time after ANF antiserum treatment. This suggests that, although ANF may participate in the regulation of electrolyte excretion, factors other than ANF may contribute to the maintenance of urinary electrolyte excretion rate during normal conditions.

Reduction of endogenous ANF concentration in the fetus did not appear to affect plasma arginine vasopressin concentration. The lack of change in face of urinary changes further supports the role of ANF in the regulation of renal function in the ovine fetus. The reduction in circulating ANF levels increased plasma angiotensin II concentration. A similar increase in plasma renin activity in adult rats after ANF antiserum treatment has been reported by Naruse et al.16 The increase in angiotensin II concentration in the present study could have been due to the short-term fall in arterial pressure after ANF antiserum injection. Hypotension in the mature ovine fetus is a potent stimulus for increasing plasma renin activity.18 Although it is tempting to speculate that ANF is inhibitory to the renin-angiotensin system as seen in the adult,22 it is difficult to separate the effect of hypotension from that of ANF blockade in the stimulation of angiotensin II release. Besides, infusion of ANF into the ovine fetus was not associated with a fall in plasma renin activity.3

In summary, this study demonstrates that in the ovine fetus plasma ANF plays a role in the regulation of normal arterial pressure and blood volume and in the maintenance of basal urinary output. Furthermore, ANF appears to have little effect in the maintenance of fetal heart rate. Finally, an interaction of ANF with the other vasoactive hormones, angiotensin II and arginine vasopressin, appears to be minimal.

A rabbit model for bacterially induced preterm pregnancy loss: Intervention studies with ampicillin-sulbactam

Robert S. McDuffie, Jr., MD,^a Sandra J. Blanton, MS,^a Robert H. Shikes, MD,^b and Ronald S. Gibbs, MD^a

Denver, Colorado

We conducted experiments with a previously described rabbit model of *Escherichia coli*—induced preterm pregnancy loss. Does at 70% gestation were inoculated hysteroscopically with 0.2 ml of *Escherichia coli* (10^5 colony-forming units per milliliter) or saline solution. Animals were randomly assigned to either receive treatment with ampicillin-sulbactam (begun 1 to 2 hours before inoculation and continued for up to 7 days) or to receive no therapy. Animals were killed after delivery or after 7 days. Saline solution—inoculated animals had no pregnancy loss. Of the *Escherichia coli*—inoculated animals, those treated with ampicillin-sulbactam had significantly fewer deliveries, fewer positive cultures, and more live fetuses than the untreated animals ($p \le 0.001$). Cultures from multiple sites, amniotic fluid prostaglandin levels, and maternal progesterone levels were obtained, and the placenta, uterus, and fetal lung were histologically evaluated. In the second phase of the study, the *Escherichia coli*—inoculated animals were treated with ampicillin-sulbactam at one of three times: at inoculation or 2 or 4 hours after inoculation. The *Escherichia coli*—inoculated does treated with ampicillin-sulbactam at or before inoculation had significantly fewer deliveries, fewer positive cultures, and more live fetuses than the *Escherichia coli*—inoculated does in which treatment was delayed 4 hours ($p \le 0.01$). (AM J OBSTET GYNECOL 1991;165:1568-74.)

Key words: Intraamniotic infection, animal model, pregnancy loss

Clinically evident intraamniotic infection is a major cause of necnatal sepsis and maternal morbidity; subclinical infection has been implicated as a cause of preterm labor. The study of these processes in human beings is limited by ethical concerns, patient availability, and confounding variables. Therefore animal models are desirable for testing hypotheses on both clinical and subclinical infection in pregnancy.

Dombroski et al. developed a rabbit model that mimicked the presumed ascending pathway for the study of bacteria-induced preterm pregnancy loss. In this model, hysteroscopic inoculation of the lower uterine horns of pregnant does at 70% gestation was performed with bacterial inocula. In utero inoculation of Escherichia coli and Fusobacterium necrophorum produced prompt and reproducible pregnancy loss as well as clinical, microbiologic, and histologic evidence of infection. On the basis of this work we tested the null hypothesis that antibiotic treatment would not decrease pregnancy loss in this rabbit model when uterine horns were inoculated with E. coli.

Material and methods

This protocol was approved by the Animal Use and Care Committee of the University of Colorado Health Sciences Center. Timed-pregnant New Zealand White rabbits (4.0 to 5.5 kg) were purchased from a vendor (Myrtle's Rabbitry, Thompson Station, Tenn.) and flown to Denver on day 14 or 15 of a 31- to 33-day gestation. The animals were housed in the Animal Resource Center of the University of Colorado Health Sciences Center. The animals were fed antibiotic-free pellets and hay and provided free access to water. The circadian cycle was 12-hour-day-12-hour-night lighting. On day 21 or 22, rabbits were anesthetized with an intramuscular injection of ketamine hydrochloride (25 mg/kg) and xylazine hydrochloride (5 mg/kg). After perineal and lower vaginal preparation with povidone-iodine solution, a hysteroscope (Storz 27020B, provided by Karl Storz Endoscopy-America Inc., Culver City, Calif.) was introduced vaginally and advanced into each cervix of the uterus didelphys. Once the hysteroscope was in the cervix, a sterile polyethylene cannula (0.06 inch outer diameter) was advanced through the operating port into the uterine horn for a distance of 6 cm. Through the tubing, 0.2 ml inoculum or pyrogen-free saline solution was injected with a tuberculin syringe.

E. coli ATCC 12014 was aerobically inoculated into thioglycollate broth and grown for 8 hours at 36° C

before concentration and washing. After centrifugation, the pellet was resuspended in sterile phosphate buffer and recentrifuged three times. A final suspension was then performed to achieve a final concentration of approximately 10⁵ colony-forming units per milliliter. Final concentrations were plated quantitatively before inoculation to confirm colony count. An aliquot remaining in each syringe was plated after inoculation to confirm viability.

Animals were randomly assigned to (1) inoculation with *E. coli* or saline solution and to (2) treatment with no antibiotic or ampicillin-sulbactam 100 mg/kg/day intramuscularly in three to four divided doses beginning 1 to 2 hours before bacterial inoculation and continued up to 7 days. After this series, 20 animals inoculated with *E. coli* were treated with ampicillin-sulbactam immediately after inoculation (0 hour), 2 hours after inoculation, or 4 hours after inoculation. In the second series, dosage was increased to 150 mg/kg/day when serum ampicillin-sulbactam levels in the initial animals showed values in the low therapeutic range.

After inoculation, animals were observed for signs of sepsis, delivery, or death. Animals were killed after delivery or after 7 days. Rectal temperatures were taken at surgery, at 24 hours after surgery, and at death.

At death, cultures were taken of blood, peritoneal fluid, amniotic fluid, and decidua and the cultures were inoculated onto 5% sheep blood agar, onto Mac-Conkey's agar, and into thioglycollate broth. Gram stains of peritoneal fluid, amniotic fluid, and decidua were prepared. Viability of remaining fetuses was noted. A blood sample for progesterone was obtained for determination by radioimmunoassay (Coat-a-Count progesterone iodine 125-labeled radioimmunoassay, Diagnostics Products Corp., Los Angeles). Pooled amniotic fluid from multiple sacs of individual does was collected for measurement of prostaglandin E2 and prostaglandin F2 metabolite by radioimmunoassay (M.J. Harper, San Antonio). These were the same prostaglandins measured in the rabbit model of Dombroski et al.1 The radioimmunoassay procedure was described by Harper et al.2 and modified by Jones et al.3 Samples were not extracted and indomethacin (10 μg/ml was added per tube). Lower uterine horn, placenta, and fetal lung sections were fixed in 10% neutral buffered formalin for histologic examination.

Outcomes were defined as follows: delivery, any fetus born before 7 days; positive culture, any organism grown in thioglycollate broth or on a plate, except for organisms grown outside the streaked area of the plate; live fetus present, any moving or breathing fetus delivered or remaining in utero; fever, temperature >104° F 24 hours after hysteroscopy. A rectal temperature of 104° F is 2 SDs above the mean in normal rabbits.

Histologic evaluation was based on the work of Mossman⁴ and Davies.⁵ A pathologic grading system of increasing severity from 0 to 4 was created by one of (R.H.S.) after one review of the slides for each of the following five items. Endometrial epithelium and glands: 0, no change; 1, rare or scattered degenerative changes with neutrophils or fibrin in glands; 2, diffuse degenerative changes with neutrophils or fibrin in glands; 3, same as grade 2 with superimposed focal epithelial or glandular necrosis; and 4, same as grade 2 with superimposed diffuse epithelial or glandular necrosis. Placental villus vessels: 0, unremarkable; 1, focal vasodilatation; 2, diffuse vasodilatation, 3, diffuse vasodilatation with focal disruption of vessels; and 4, diffuse vasodilatation and disruption of vessels. Neutrophilic infiltrate of membranes: 0, none; 1, rare sites; 2, occasional; 3, frequent; and 4, diffuse involvement. Necrosis of membranes: 0, none; 1, rare; 2, occasional; 3, frequent; and 4, diffuse involvement. Endometrial stromal edema: 0, none; 1, mild and focal or diffuse; 2, moderate and focal; 3, moderate and diffuse; and 4, marked and diffuse.

Data were entered into the SAS program (Statistical Analysis Systems, Inc., Cary, N.C.). Categoric data were analyzed by Fisher's exact test. Continuous data were analyzed by two-way analysis of variance and Student—Newman-Keuls test of multiple comparisons. Where assumptions were not met, nonparametric analysis consisted of the Kruskal-Wallis procedure. A *p* value of <0.05 was considered to be significant.

Results

Fifty animals underwent hysteroscopy. There were no uterine perforations. One maternal death occurred in an untreated animal 20 hours after inoculation with $E.\ coli$. Of nine rabbits receiving saline inoculum, four were untreated and five received ampicillin-sulbactam. There were no differences in outcome between treated and untreated saline solution—inoculated animals; therefore the two groups were analyzed together. When $E.\ coli$ —inoculated groups were compared, animals treated with ampicillin-sulbactam had fewer deliveries, fewer positive cultures, and more live fetuses than untreated animals (Table I). The final inoculum count varied from 2×10^4 to 6×10^6 . No differences in outcome were apparent for inoculum size.

Of animals at 22 to 24 hours, those inoculated with $E.\ coli$ and treated with ampicillin-sulbactam had fever less frequently than untreated animals. The only maternal death was excluded. None of nine saline solution–inoculated animals developed fever. Of $E.\ coli$ —inoculated animals, seven of nine (78%) untreated animals developed fever and none of the 11 (0%) treated animals developed fever (p < 0.001).

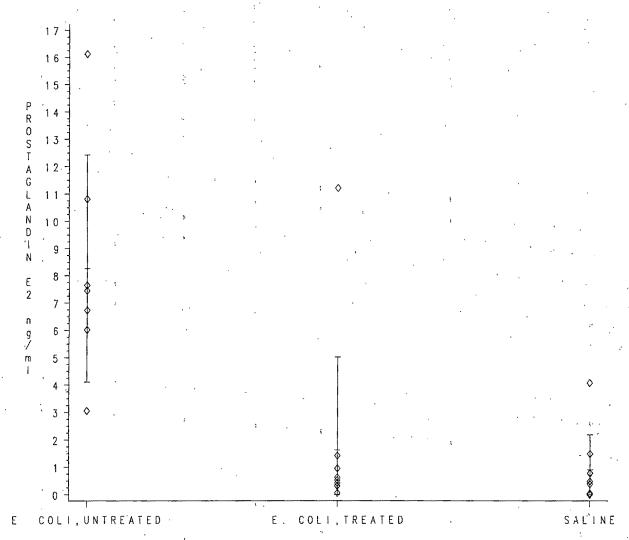

Fig. 1. Amniotic fluid prostaglandin E_2 (mean \pm SD) as related to intrauterine inoculum and treatment. Values for *E. coli*—untreated group are significantly higher compared with *E. coli*—treated group (p < 0.05) by Kruskal-Wallis procedure.

^{*}Fisher's exact test.

Prostaglandin E_2 and prostaglandin F_2 metabolite levels were higher in untreated E. coli—inoculated animals than in those treated with ampicillin-sulbactam (Figs. 1 and 2). Hemolysis was noted in five of seven amniotic fluid samples in untreated E. coli—inoculated

animals; in this group no differences were seen when hemolyzed and nonhemolyzed amniotic fluid prostaglandin levels were compared.

Progesterone levels were significantly lower in untreated E. coli—inoculated does than in saline solution—

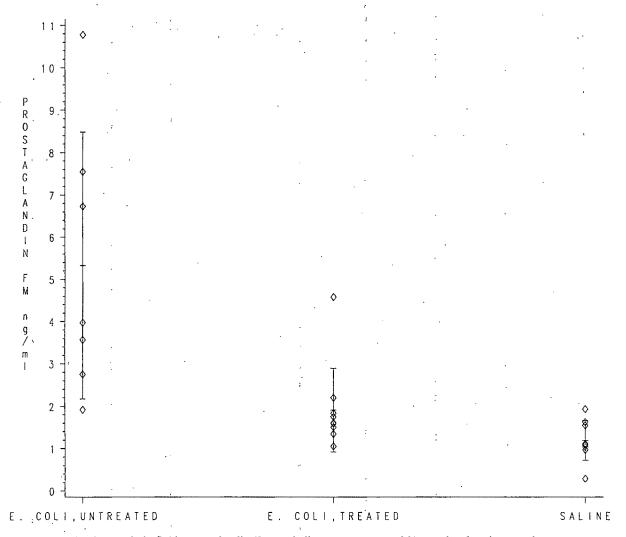

Fig. 2. Amniotic fluid prostaglandin F_2 metabolite (FM) (mean \pm SD) as related to intrauterine inoculum and treatment. Values for E. coli—untreated group are significantly higher compared with E. coli—treated group (p < 0.05) by Kruskal-Wallis procedure.

Table II. Positive cultures by site and treatment for E. coli inoculum

	E. coli inoculum					
	Untre	ated	Treated			
Site	No.	%	. No.	%

inoculated controls. No significant difference was seen between progesterone levels of treated and untreated *E. coli*—inoculated rabbits, although the mean value of the untreated group was lower (Fig. 3).

Of animals inoculated with E. coli and not receiving ampicillin-sulbactam, cultures from all animals grew

this bacterium from multiple sites as the only organism. Furthermore, 9 of 10 animals had positive blood cultures (Table II). Three treated $E.\ coli$ —inoculated rabbits had positive cultures; in each of these, the culture from only one site was positive. Two of these grew $E.\ coli$ and one grew α -streptococci.

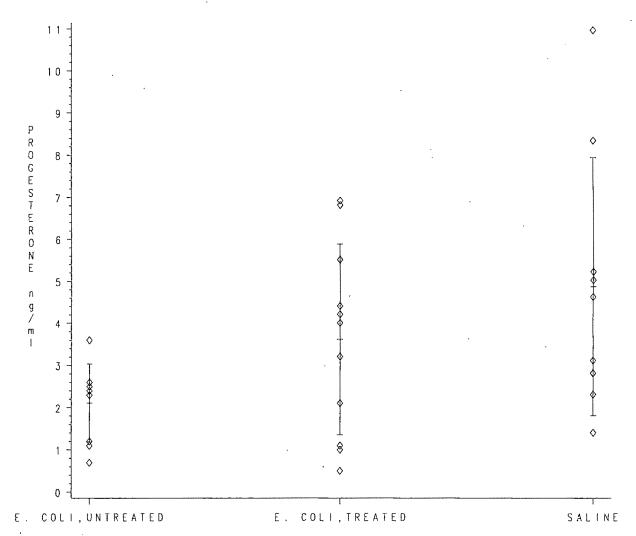

Fig. 3. Maternal serum progesterone (mean \pm SD) as related to intrauterine inoculum in treatment. Values for *E. coli*—untreated group are significantly lower compared with saline solution group (p < 0.05) by Kruskal-Wallis procedure. *E. coli*—untreated group was not significantly different from *E. coli*—treated group.

Table III. Pathologic grading by intrauterine inoculum and treatment

	Inoculum					
		E. coli				
Item	Saline solution (n = 9) (% grade > 0)	Untreated $(n = 9)$ (% grade > 0)	þ	Treated $(n = 11)$ (% grade > 0)		
Epithelium and glands	0	100	< 0.001	18

NS, Not significant.

Results of the pathologic grading of the five parameters for each intrauterine inoculum are shown in Table III. In general, *E. coli*—inoculated animals that did not receive ampicillin-sulbactam had more severe changes

than either saline solution— or *E. coli*—inoculated animals treated with ampicillin-sulbactam. Untreated *E. coli*—inoculated animals were often grade 3 or 4 in multiple items. Treated *E. coli*—inoculated animals that

Oulcome	Hours from E. coli inoculum to treatment							
	1 to -2		0		2		4

Table IV. Outcome by E. coli inoculum and time of treatment

did not deliver did not have any grades higher than I. Saline solution-inoculated animals had only rare histologic changes. Two other findings were of note. First, there were no pathologic signs of infection in the lung fields; second, eosinophils were seen in the endometria of all untreated E. coli-inoculated animals, whereas they were not seen in any saline solution-inoculated animals.

In the second phase of the study, 4 animals were treated with ampicillin-sulbactam at inoculation with E. coli, 6 at 2 hours after inoculation, and 10 at 4 hours after inoculation. Animals inoculated with E. coli and treated at or before surgery had fewer deliveries, fewer positive cultures, and more live fetuses present than those treated 4 hours after inoculation (Table IV). Undelivered animals in the 2- and 4-hour groups had both live and dead fetuses in utero at death. In these cases, live fetuses were more often present in the distal uterine horns.

Comment

These experiments were designed to extend observations in the rabbit model developed by Dombrowski et al.1 to test whether antibiotic therapy would result in greater fetal salvage than no therapy. Through the use of saline solution controls and treated and untreated E. coli-inoculated groups, we confirmed that (1) the hysteroscopy itself did not result in pregnancy loss and (2) E. coli inoculation of pregnant uterine horns resulted in reproducible pregnancy loss. Our new observations are that treatment with ampicillin-sulbactam at or before inoculation resulted in improved outcome and that treatment 4 hours after inoculation led to worse outcomes than preinoculation treatment. The last finding is consistent with the classic work of Burke⁶ in which penicillin treatment of induced staphylococcal dermal lesions was ineffective after 4 hours.

Previous animal models of pregnancy loss have included intraperitoneal endotoxin,7 intravenous endotoxin,8.9 intraamniotic bacterial inoculation,10-12 and intracervical bacterial inoculation.13 Our premise was that hysteroscopic inoculation would closely mimic the presumed ascending pathway. Support for ascending in-

fection occurred in our experiments in which the antibiotic was delayed 2 or 4 hours after inoculation. If live fetuses were found after 7 days, they were present in the distal horns.

Comparison of treated and untreated groups revealed a model of overwhelming infection. By every measure of infection, including outcome, cultures, fever, and prostaglandin levels, we observed amelioration by administration of ampicillin-sulbactam before inoculation.

Prostaglandin levels were higher in untreated than in treated animals. We speculate that this could be caused by production of phospholipase A2 by E. coli,14 activation of amnion cells by endotoxin,15 or endotoxin activation of decidual macrophages to produce cytokines. Progesterone levels, which were not different in treated and untreated rabbits, were lower in untreated animals compared with saline solution controls. It is difficult to separate cause from effect in this situation. The numbers of animals were small, and the SDs were large.

Histologic findings, though variable in range in each of the five categories, confirmed the presence of significant inflammation and necrosis in the endometria and membranes of most untreated cases. Sections of treated undelivered animals were generally free of significant inflammation and necrosis in the endometria and membranes. Thus histologic evaluation correlated well with clinical outcome.

In spite of these dramatic findings, we recognize the limitations of the model when applied to human beings. First, antibiotics are begun at or before inoculation of organisms in the model (usually not the case in clinical medicine). Second, anatomic and pharmacokinetic considerations may not be comparable. Third, the rabbit is notoriously progesterone dependent in its mechanism of labor.16 Therefore, whereas the eradication of E. coli with improved pregnancy outcome is encouraging, it is premature to recommend routine treatment of intraamniotic infection without delivery in human beings on the basis of this work. Nevertheless, improved outcomes are reported in pregnancy loss models in the rhesus monkey,17 and case reports exist of successful

^{*}p < 0.01 When treatment ≤ 0 hour compared with 4 hours.

 $[\]dagger p$ < 0.001 When treatment ≤0 hour compared with 4 hours.

treatment of intraamniotic colonization¹⁸ and infection without delivery in human beings.¹⁹ Although the standard approach to intraamniotic infection is antibiotic treatment and delivery, our data imply that antibiotic treatment alone may suffice provided it is begun very early, before clinical manifestations of infection (i.e., in the subclinical period as manifested by preterm labor).

We have confirmed that hysteroscopic inoculation of *E. coli* into pregnant rabbits results in reproducible pregnancy loss accompanied by microbiologic and histologic evidence of infection. Furthermore, treatment with ampicillin-sulbactam at or before inoculation results in improved pregnancy salvage when compared with untreated animals or animals treated 4 hours after inoculation.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of \$61.00 for domestic, \$88.27 for Canada, and \$84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders*. Contact Mosby—Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

LETTERS TO THE EDITORS

Hypertriglyceridemia in small-for-gestational-age fetuses

To the Editors: I read with great interest the article by Economides et al. (Economides DL, Crook D, Nicolaides KH. Hypertriglyceridemia and hypoxemia in small-for-gestational-age fetuses. Am J Obstet Gynecol. 1990;162:382-6). The authors found elevated plasma triglyceride concentration in samples obtained by cordocentesis for small-for-gestational-age fetuses.

One month earlier we described the increase of cord blood triglyceride concentration in small-for-gestational-age infants born to mothers with placental insufficiency. The mechanism of triglyceride increase in those cases is not well understood. I suggest that chronic fetal hypoxia caused by placental insufficiency is associated with a substantial release of catecholamines. Increased secretion of catecholamines leads to lipolysis and results in elevated blood fatty acid level. The fetal liver takes up some of the excess fatty acid and synthesizes endogenous triglycerides that appear in the fetal serum.

It has been found that the duration of fetal hypoxia must be considerable, perhaps even an hour or more, for it to result in hypertriglyceridemia.²

I proposed that the level of cord blood triglyceride may prove to be a useful indicator of chronic fetal hypoxia.

Splitting hairs about splitting muscles

To the Editors: Helmkamp and Krebs (Helmkamp BF, Krebs H-B. The Maylard incision in gynecologic cancer. Am J Obstet Gynecol 1990;163:1554-7) recently presented data substantiating the value of the Maylard abdominal incision. This article was timely, nicely done, and welcome. The Maylard technique, however, is not a "muscle-splitting" incision. It is, rather, a muscle-cutting procedure. Quoting Condon¹ in his chapter on appendicitis in Sabiston's Textbook of Surgery, "... the muscle-splitting incision (McArther-McBurney) is the time-honored approach and one widely used today. ... Its advantage is that separation of muscles in the line of their

fibers produces a wound that does not depend entirely upon sutures for restoration of tissue continuity." Surgical transection of the rectus muscles does not fit this description.

The risk of subfascial hematoma and the associated need for a subfascial drain are related to the creation of a closed space between the fascia and parietal peritoneum. Both can be eliminated by meticulous hemostasis and by allowing the parietal peritoneum to remain open and unsutured.²

Reply

To the Editors: Thank you very much for your comments regarding our recent article. I agree that "musclecutting" more accurately describes the Maylard technique because the incision through the rectus muscles is perpendicular to the muscle fibers rather than parallel.

I do not suture the posterior rectus sheath in closing vertical and Pfannenstiel incisions. If you do likewise with the Maylard incision and have had no wound complications, it may be possible to eliminate the subfascial drain as you suggest.

Effects of leukotrienes in the placental vasculature

To the Editors: Thorp et al. (Thorp JA, Walsh SW, Brath PC. Comparison of the vasoactive effects of leukotrienes with thromboxane mimic in the perfused human placenta. Am J Obstet Gynecol 1988;159:1376-80) have clearly shown that leukotrienes B₄ (LTB₄) and C₄ (LTC₄) do not exert major effects on the placental vasculature except at high doses (>1 μg per bolus injection). It is, however, clear from previous work that prostaglandins may have more potent effects on angiotensin II constricted placental vessels than when added alone¹; therefore we have investigated the effects of coadministration of LTB₄ or LTC₄ (5 to 500 ng per bolus injection) with angiotensin II (5 μg per bolus injection) on placental perfusion pressures. The perfusion system used in this study has been described.¹

Only the highest bolus injection (500 ng) of LTB₄ or LTC₄ increased the perfusion pressure (LTB₄, 17.8 ± 0.3 mm Hg; LTC₄, 6.2 ± 2.9 mm Hg; mean \pm SEM, n = 6); this finding agrees with the earlier study by Thorp et al. Angiotensin II (5 µg per bolus injection) stimulated a greater increase in perfusion pressure (34 \pm 8 mm Hg, n = 13); this was not affected by coadministration of 500 ng LTB4 or LTC4 $(36.7 \pm 13.3 \text{ and } 26.2 \pm 7.6 \text{ mm Hg}, n = 6, \text{ respec-}$ tively). These results support the contention of Thorp et al. that leukotrienes are not active modulators of the placental vasculature; it also demonstrates that the leukotrienes have no effect on contracted placental vessels. It is thus apparent that leukotrienes and prostaglandins differ markedly in their effects on the placental vasculature.

Reply

To the Editors: We are pleased that Sullivan et al. have confirmed our results that leukotrienes are relatively weak vasoconstrictors in the human placental vasculature even when the vessels are first constricted with angiotensin II. It appears that most compounds other than thromboxane are relatively weak vasoconstrictors in the human placenta. This probably serves to protect the placenta from vasoconstriction and assure adequate perfusion for placental and fetal growth. As more information accrues, it appears that major vasoconstrictive disorders of the placenta such as preeclampsia involve an imbalance between thromboxane and prostacyclin. We believe that understanding the mechanisms regulating placental production of thromboxane and prostacyclin is extremely important and that research studies directed at uncovering these mechanisms will provide valuable information concerning the eventual treatment of various vasoconstrictive disorders of pregnáncy.

Infertility and eating disorders

To the Editors: We were very interested to see the results of the recent study of the eating behavior of women initially seen for infertility (Stewart DE, Robinson GE, Goldbloom DS, Wright C. Infertility and eating dis-

orders. AM J OBSTET GYNECOL 1990;163:1196-9). These results complement our findings. After administering the Bulimia Investigatory Test Edinburgh² (BITE) questionnaire to a large sample of women attending a gynecologic endocrinology clinic (n = 262), we found abnormal eating behavior in 24% of the population. Interestingly, the rate of abnormal eating behavior was significantly higher (p = 0.02) in women with ultrasonographic diagnoses of polycystic ovary syndrome (n = 153) than in a comparison group of women (n = 109) with other causes of menstrual disturbance. Thirty-one percent of women with polycystic ovary syndrome had abnormal BITE scores compared with 14% of women with other endocrinopathies. We would like to know if Stewart et al. analyzed their data according to diagnosis.

We strongly support the recommendation of Stewart et al. that the eating behavior of women attending fertility clinics or presenting with menstrual disorders be assessed. Abnormal behaviors such as binge eating or fasting should be rectified with appropriate therapy such as the program for bulimia described by Lacey.³ Pregnancies that occur in women with anorexia after ovulation resumes because of weight gain are more successful than pregnancies that occur when ovulation resumes because of pharmacologic stimulation.⁴ The 26-item Eating Attitudes Test⁵ is a suitable screening instrument. However, we found the BITE to be more sensitive and specific for bulimic behavior.

Reply

To the Editors: It is indeed interesting that McCluskey et al. have recently found a prevalence similar to that reported by us of abnormal eating behavior in women attending a British gynecologic endocrinology clinic. However, although our women with abnormal menses scored significantly higher (p=0.0001) on the 26-item Eating Attitudes Test (EAT-26) than women with normal menses, after full investigation we found only 17% to have polycystic ovary syndrome.

McCluskey et al. state that the BITE is more sensitive and specific for bulimic behavior, which may account

for their slightly higher prevalence rates of abnormal eating behavior. Diagnostic criteria may also influence these rates: We adhered to the relatively strict criteria of the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders. We also confirmed all possible cases identified by the screening instrument with a clinical interview, and we excluded false positives. The choice of screening instrument is clearly important. We note that other eating disorder investigators have expressed concern about the BITE,2 but we have no experience with that instrument. However, in this study we did compare the EAT-26 and another common eating disorder questionnaire, the Eating Disorder Inventory, which measures pathologic behavior across a broader range of psychologic and behavioral dimensions associated with eating disorders.3 Although these data were deleted for the sake of brevity in our article, we found the EAT-26 to be superior to the Eating Disorder Inventory in terms of sensitivity, specificity, brevity, and ease of scoring. The main source of error in both instruments, however, was denial of eating problems by some patients or false-positive results in overweight women who were unhappy, dieting, and preoccupied by food.

We again emphasize that body weight is often a poor predictor of eating disorders and that careful clinical inquiry is vital. Our earlier work indicates that women with eating disorders that remain unresolved before pregnancy have more problems during pregnancy, lower maternal weight gain, and smaller babies with lower Apgar scores than women whose eating disorders are in complete remission. The identification of eating disorders in reproductive endocrinology clinics is both cost-effective and an important opportunity for primary prevention.

Indomethacin induces hypertensive crisis in preeclampsia irrespective of prior antihypertensive drug therapy

To the Editors: Schoenfeld et al. report preeclampsia being aggravated in two patients treated with β -adren-

ergic receptor blockers after ingesting indomethacin; the authors correlate this hypertensive crisis with antagonism of the β-adrenergic receptor blockers by indomethacin (Schoenfeld A, Freedman S, Hod M, Ovadia Y. Antagonism of antihypertensive drug therapy in pregnancy by indomethacin? Am J Obstet Gynecol 1989;161:1204-5).

I believe hypertensive crisis can occur in preeclampsia after ingestion of any prostaglandin synthetase inhibitor drug (aspirin, indomethacin) irrespective of the antihypertensive drug regimen, if any. Vasodilatory prostaglandins produced by the kidneys in the state of hypoperfusion maintain renal perfusion by dampening the vasoconstrictive effect of angiotensin on renal arteries. Indomethacin blocks prostaglandin synthesis and renders renal vasculature vulnerable to the constrictive effect of angiotensin II. Vasoconstriction of renal arteries results in renal hypoperfusion manifested by hypertensive crisis.

Animals given indomethacin and subjected to slight hemorrhage may have rapidly occurring severe renal damage.¹

Therefore it is wise to avoid all prostaglandin synthetase inhibitor drugs in women with pre-eclampsia.

Reply

To the Editors: We thank Dr. Mousavy for his letter regarding our article. We agree with his statement about the interference with antihypertensive drugs by non-steroidal antiinflammatory drugs. In our article we stated that "indomethacin (and other) nonsteroidal antiinflammatory drugs vitiate the action of antihypertensive drugs and that in some patients the hypertensive response may be severe."

Dr. Mousavy's hypothesis, which deals with the antiprostaglandin synthesis mechanism, is based on the work of Vane¹ and likely explains a good portion of the action of the nonsteroidal antiinflammatory drugs. We would like to add that other, recently published^{2, 3} modes of action should be considered.

OB GENERALISTS & SUBSPECIALISTS IN HIGH-RISK OBSTETRICS

18 5 /00

The Saudi Arabian Oil Company's (SAUDI ARAMCO) Medical Services Organization in Saudi Arabia needs an Obstetrician/Gynecologist with a subspecialty in maternal fetal medicine. American Board Certification and 2 years' experience after residency required. Strong leadership qualities as well as experience in both a professional and administrative capacity are preferred.

Saudi Aramco's 483 bed Dhahran Health Center has all major specialties and most subspecialties. The company also operates out-patient and emergency care clinics in its 3 surrounding communities. Saudi Aramco employees and their dependents comprise the 230,000 patient population. Our Blood Bank is accredited by the American Association of Blood Banks. Consulting liaisons exist with the WHO in Geneva and the Centers for Disease Control in Atlanta.

As a Saudi Aramco employee, you will receive a competitive base compensation package as well as an expatriate premium. Additional benefits include noncontributory group life insurance, company-matched savings, free medical care at Saudi Aramco's hospital and clinics, housing inside a company community, and extensive recreation facilities and activities. Your eligible children will be enrolled in company schools, comparable to U.S. private schools. Annually, there are up to 13 company holidays plus you will be eligible for 36 calendar days of vacation, with round-trip airfares to the U.S. or Canada for you and your family.

For consideration, CALL OUR 24 HOUR, 7 DAYS PER WEEK TOLL-FREE NUMBER LISTED BELOW:

We're offering a competitive salary, and occurrence malpractice premiums are fully paid. What's more, there's an ownership opportunity after the initial employment period. The position will be available by July, 1992 or earlier.

This position has a lot to offer. In a state that has everything.

The group is affiliated with a 330-bed hospital with a Level II Nursery in one of scenic New England's fastest-

growing areas, just one hour from Boston.

Reply with CV to: Office of Physician Services,
Catholic Medical Center, 100 McGregor Street,
Manchester, NH 03102. (603) 626-2879. This could
be everything you always wanted.

SHOCK YOUR FAMILY & FRIENDS!

Tell them you're looking at practicing in eastern North Dakota or western Minnesota! Our countrypolitan lifestyle includes commutes of up to 9 minutes, 6car traffic jams, unlocked doors, exceptional schools, bagging the limit in fish and game or just dangling your feet off the dock. The Dakota Clinic is a 154-person multispecialty group looking for OB/ GYN physicians. Specific sites include Fargo and Jamestown, North Dakota, as well as Detroit Lakes or Park Rapids, Minnesota. Excellent salary and benefits with stockholder opportunity after two years. There are minimal buy-in requirements. To receive our video and community practice information kit, call Dick Reis at 1-800-342-4926, or write: Dick Reis, Manager, Recruiting, Dakota Clinic, Ltd., 1702 South University Drive, Fargo, ND 58103.

Generalist Obstetrician/Gynecologist Maternal/Fetal Medicine Subspecialist Gynecologic Oncologist Faculty Positions

The James H. Quillen College of Medicine of East Tennessee State University (ETSU) is seeking a board certified/eligible General Obstetrician/Gynecologist and a board certified/eligible Maternal/Fetal Medicine (Perinatology) subspecialist and a board certified/eligible Gynecologic Oncologist. These positions offer an excellent opportunity combining research, teaching and private practice with a faculty position at the Assistant/Associate Professor level. Salaries are very competitive and fringe benefits are excellent. The Medical School is located in the Tri-Cities area of Northeast Tennessee in a beautiful section of the Appalachians and within sight of the Blue Ridge Mountains. The area has excellent hunting, fishing, and camping with multiple ski resorts at your doorstep. The Tri-Cities combines good schools and rural living in a safe, beautiful environment. Yet, the medical referral base consists of 1.3 million people within a 50 mile radius of the Medical School. Send curriculum vitae to:

Frederick R. Jelovsek, M.D.
Professor and Chairman, Dept. OB/GYN
James H. Quillen College of Medicine
East Tennesee State University
P.O. Box 19570A
Johnson City, TN 37614-0002

ETSU is an AA/EO employer.

CENTRAL NEW YORK

Excellent opportunity for board-certified/board-eligible Obstetrics and Gynecology Physician. Lovely family-oriented community with four-season recreational and cultural activities. Send CV or contact: Civita Brown, Director, Medical Education, Clinical Medical Network, Utica College of Syracuse University, 1600 Burrstone Road, Utica, New York 13501.

(315) 792-3333

The Department of OB/GYN at the Washington Hospital Center is currently seeking another full time Perinatologist for their Division of Maternal Fetal Medicine to work with the Director of Obstetrics/Maternal Fetal Medicine.

The Washington Hospital Center is a 900 bed tertiary care teaching facility with a compliment of 16 residents in the Department of OB/GYN. Currently the Department of OB/GYN delivers approximately 3,000 babies annually and because of its urban setting, the incidence of high risk pregnancies is approximately 40%.

There is an active Antepartum Surveillance unit and Prenatal diagnostic unit with OB/GYN ultrasound lab available in the division of Maternal Fetal Medicine. Invasive prenatal diagnostic procedures are performed in the division.

Excellent opportunity for active clinical research and resident teaching. We are interested in applicants who are qualified in Maternal Fetal Medicine, board eligible/board certified. Experience in OB/GYN Ultrasound and invasive prenatal diagnostic testing preferred.

Salary is commensurate with qualifications and experience.

Please send a Curriculum Vitae to Dr. Shailini Singh, Director, Obstetrics/Maternal Fetal Medicine, Washington Hospital Center, 110 Irving Street, NV, Suite 5W40, Washington, DC 20010 or Fax to 202/877-6590.

PERINATOLOGIST

Perinatologist sought to develop a program of research in maternal-fetal medicine. The successful applicant will be primarily responsible for initiating research in both basic science and in clinical and epidemiologic aspects of maternal-fetal medicine in a university-based department of Obstetrics and Gynecology. The position is supported by two full-time faculty members in the division of maternal-fetal medicine that provide a strong foundation in clinical care and regional outreach. Deadline for applications is January 1, 1992.

Send C.V. to:

Search Committee c/o Millard Simmons, M.D. Chief, Division of Maternal-Fetal Medicine Department of Obstetrics and Gynecology West Virginia University, School of Medicine Health Sciences Center Morgantown, WV 26506

West Virginia University is an Equal Opportunity/Affirmative Action Institution.

AN EQUAL OPPORTUNITY EMPLOYER

Group Health has shown that quality care at a reasonable price is not an impossible dream.

The New York Times, May 2, 1991

66Group Health is my model for the future.99

Arnold Relman, MD, retired editor, New England Journal of Medicine

€ Escalating malpractice costs make starting your own practice almost impossible. At Group Health, I earn a good salary and have time to enjoy it. 99

Ronald Helm, OB/GYN
Tacoma Specialty Clinic

Group Health has been quietly revolutionizing health care since 1947. With the single premise that quality health care needn't be expensive, we've built one of the most respected managed care systems in America. Our physicians can concentrate their efforts on the practice of medicine without worrying about their next paycheck. This improves the relationship between doctor and patient, resulting in better health care.

Discover for yourself the future direction of health care. Call us toll-free at (800) 543-9323. Group Health is an equal opportunity employer.

enough is enough

Power to suppress estradiol to levels that result in effective relief

- Lowers serum estradiol to near menopausal levels within approximately 1 month, and maintains those levels throughout the 6-month course of therapy.*
- 92% of patients (n = 143) were symptom-free or had only mild symptoms following a 6-month course of therapy.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL. There is a small loss in bone density with 6-month treatment, some of which may not be reversible. During one treatment period the bone loss should not be important. 'Gonadotropin-releasing hormone analog. Please see brief summary of prescribing information on next page.

Control in the management of hypoestrogenic and therapeutic effects

- A small impact on bone,[†] as well as a predictable and manageable hypoestrogenic profile.
- Lets you terminate treatment immediately should that be required for any reason, unlike the depot form of GnRH[‡] therapy.

Setting The Pace In Endometriosis Therapy

BRIEF SUMMARY

SYNAREL® Nasal Solution contains natarelin acetate (2 mg/mL, expressed as natarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water. INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older

treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

are oreas recurry. WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment preg-

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant
during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve sportaneously or may require drug discontinuation or surgery.
Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should not use SYNAREL
if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the
dose. Coursel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL
if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are altergite to any of its ingredients. 3. Sale
use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during
treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician
A Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation
occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6
month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should
not be important. In patients with major risk factors for foecreased bone mineral control, i.e., chronic alcohol and/or
tobacco use,

gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 550 times the maximum recommended human irransal dose respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in Harderian gland tumors in males and an increase in the relative times and the relative time of the relative times and the relative time of the relative times and the relative times and time of the relative bioavailability to sentility of rettility of rettility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: Pregnancy Category X. Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 tetuses at the hipsels dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 µg/kg/day and 018 µg/kg/day, respectively, failed to demonstrate an increase in fetal mortality and a decrease in fetal wortality and a decrease in fetal wortalities.

**Warset State Vand Cate State Vand Category Category Category Category Category Category Categor

Nursing Mothers: Itis not known whether SYNAPILL is excreted in human milk, Because many urups are excreted in human milk, and because the effects of SYNAPIL or lactation and/or the breasted child have not been eletermined, SYNAPIL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAPIL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenile: hot flashes (SYNAPIL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insominia (8%, 49%), Androgenic: area (13%, 20%), raylogia (10%, 23%), effective breast size (10%), 69%), ebema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%), Local: nasal irritation (10%, 3%); Miscellaneous: depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthrafigal, in clinical trials, immediate hypersensitivity thought to be possibly or probably related to naferelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total wortebral bone mass, measured by quantitative computed tomography (OCT), decreased by an awerage of 87% and 43%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment, the average trabecular bone dernsity and total bone mass were 4.9% and 3.3% less than pretreatment levels. Breatment Mean total vertebral amass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decreased in the mineral content recommended or monits of impresence of other instantiana, and the first total bone loss.

Changes in Laboratory Values: Plasma enzymes. During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids: At enrollment and at end of treatment, 9% of patients on SYNAREL 400 µg/day and 2% on danazol had total

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 µg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL. Mean (±SEM) pretreatment values for total cholesterol from all patients were 1918 (4.3) mg/dL in the SYNAREL group and 1931 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 2077 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant (p < 0.05) in both groups.

Triglycer/des were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) com-

patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 90 mg/dL) compared with 15% of those on danazol. There was no increase in the LDLHDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDLHDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with elevations of plasma of the properties of the matocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD State University of New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Yes! Please begin my subscription to Current Problems in Obstetrics, Gynecology and Fertility (6 issues per year).

J5290F7B

NORPLANT SYSTEM levonorgestrel implants

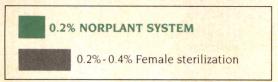

Six reasons why you can feel comfortable recommending it to your patients

Effectiveness comparable to tubal ligation

Although no contraceptive is 100% effective, the NORPLANT SYSTEM is one of the most effective forms of birth control ever developed. The average annual gross pregnancy rate over a five-year period is less than 1%.

Lowest expected and typical failure rates with NORPLANT SYSTEM vs. sterilization during first-year use

Adapted from Trussell I, et al.

Long-term convenience... estrogen-free

NORPLANT SYSTEM, a progestin-only contraceptive, is an excellent option for women desiring a long-term method. Its effectiveness lasts for five years and is not dependent on compliance.

Reversible, with prompt return to previous level of fertility

NORPLANT SYSTEM is reversible at any time; the contraceptive effect ceases when the capsules are removed.

In one study, 40% of women wanting to conceive did so within 3 months of removal, 63% by 6 months, 76% by 12 months, and 90% by 24 months.²

High patient acceptance despite menstrual pattern changes

NORPLANT SYSTEM causes menstrual irregularities (the most common complaint),* which occur in many women during first-year use and diminish over time. Only 9.1% of patients discontinued during first-year use due to these changes.^{3†}

Women who are thoroughly informed of potential menstrual changes and side effects are more tolerant of them when they occur.⁴

Well-received, well-liked by American women

One study of 140 users revealed that 94% were satisfied with NORPLANT SYSTEM, 91% recommended it to their friends, and 74% wanted to use it again.⁵

A 10- to 15-minute office procedure

A local anesthetic and a small 2 mm incision...little or no discomfort during insertion...proper placement should not leave a noticeable scar...in most cases sutures are not needed.

- *Serious as well as minor side effects may occur (see prescribing information).
- † Based on multicenter trials of 2,470 women.

Please see brief summary of prescribing information on adjacent page.

Lasts 5 years...yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage
The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

Active throughpublishing at throughpublic disorders. 2. Undiagnosed absormal position.

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver turnors. 5. Known or suspected carcinoma of the breast.

tumors. 5. Known or suspected carcinoma or the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. Bleeding Irregularities — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the cansules must be removed. whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. Delayed Follicular Atresia — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles that are clinically indistinguishable from varian cysts.

follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be

required.

3. Ectopic Pregnancies — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out extonic pregnancy in any patient pregenting with lower-abdominal pain.

ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. Breast-feeding — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after

Foreign-body Carcinogenesis — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to

6. Thromboembolic Disorders — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. Cigarette Smoking — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in yourne cure 25 vocased.

quite marked in women over 35 years old.

2. Elevated Blood Pressure — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. Thromboembolic Disorders and Other Vascular Problems — An increased risk of

thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

relative risk is 4- to 11-foid injoher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is

Induction (MI). An increased risk of MI has been attributed to combined of use. Insist thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levynorgestic-containing OCs.

levonorgestrel-containing OCs.

4. Carcinoma — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. Hepatic Tumors — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal

hemorrhage.

6. Ocular Lesions — Retinal thrombosis is associated with OC use and is believed to be related to 6. Ocular Lesions — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately. 7. Use Before or During Early Pragnancy — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. Gallbladder Disease — Early studies reported an increased lifetime relative risk of gallblade surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

Precautions
GENERAL

1. Physical Examination and Follow-up — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and least annually during its use. Exams should include special reference to the implant site, bloo pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant labor tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules silve monitored with particular care.

be monitored with particular care.

2. Carbohydrate Metabolism — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appea minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYS Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Sc progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See

Warnings.)

3. Liver Function — Consider removing capsules if jaundice develops. Steroid hormones may poorly metabolized in patients with impaired liver function.

4. Fluid Retention — Steroid contraceptives may cause some degree of fluid retention. Presc

with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid

Emotional Disorders — Consider removing capsules if significant depression occurs since symptom may be drug-related. Observe carefully those with history of depression and consic

removal if depression recurs to a serious degree.

6. Contact Lenses — Contact-lens wearers who develop visual changes or changes in lens

tolerance should be assessed by an ophthalmologist.

7. Insertion and Removal — Insertion is advised during the first 7 days of the cycle or immer following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-fi women. Follow insertion and removal instructions closely. Healthcare professionals are stror advised to be instructed in the procedures before they attempt them. Proper insertion just un skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. capsules cannot be removed a first attempt, attempt, removal attempt when the site has headed.

Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occu implant site but is usually reversible following removal. See Full Prescribing Information for Detailed Insertion/Removal Instructions.

8. Infections — Implant site infection has been uncommon (0.7%); aseptic technique and pre insertion/removal reduces possibility of infection. Institute treatment if infection occurs; removables it infection process.

capsules if infection persists.

capsules if infection persists.

9. Expulsion — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replace Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. Provisions for Removal — Advise women that capsules may be removed at any time for reason. Personnel instructed in removal technique should perform removal on request or at to of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disea Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has beer reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYS users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptak

increased.

CARCINOGENESIS: See Warnings section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See Warnings section and Full Prescribing Information.

NURSING MOTHERS: See Warnings section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to try patient. Advise patients that Prescribing Information is available upon request. Inform prosper users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed contraceptions, and benefits associated with insertion/removal procedures. from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions
The following have been associated with the NORPLANT SYSTEM during first year of use: ma bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregulz (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain o itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).
Controlled clinical studies suggest that the following, occurring during the first year, are prob associated with NORPLANT SYSTEM use; headache; nervousness; nausea; disziness; adnexa enlargement; dermatitis; acne; change of appetite; mastalgia; weight qain; hirsutism, hypertri and scalp-hair loss. The following were reported with a frequency of 5% or greater during the year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis. musculoskeletal pain; abdominal discomfort; leukorrhea; vaoinitis,

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregula Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic* capsules, each containing 36 mg of the pro levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six cap should be performed during the first 7 days of the onset of menses by a healthcare profession instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midp of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanilike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. (See Full Prescribing Information for Detailed Insertion/Removal Instructions.) CI 4064-1 12/10/90

PAPERS OF THE SOCIETY FOR GYNECOLOGIC INVESTIGATION

Elevated fetal plasma lactate produces polyhydramnios in the sheep

1595

Theresa L. Powell, PhD, and Robert A. Brace, PhD

San Diego, California

Intravenous infusion of sodium lactate into near-term fetal sheep for 3 days resulted in polyhydramnios but not hydrops fetalis.

Left thoracic duct lymph flow responses to angiotensin II or atrial natriuretic factor infusion in the ovine fetus

1607

Robert A. Brace, PhD, and Robert L. Andres, MD

San Diego, California

The current study suggests that angiotensin II may stimulate and atrial natriuretic factor may suppress lymphatic function in the ovine fetus.

Oral-nasal membranes are not the major route for fetal absorption of amniotic fluid arginine vasopressin

1614

William M. Gilbert, MD, Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD San Diego, California

The ovine fetal oral-nasal membranes do not appear to be a route of significant absorption of intraamniotically injected arginine vasopressin relative to absorption by the intramembranous pathway.

Amniotic fluid volume response to esophageal occlusion in fetal sheep

1620

Yuji Fujino, MD, Connie L. Agnew, MD, Peter Schreyer, MD, M. Gore Ervin, PhD, Dan J. Sherman, MD, and Michael G. Ross, MD

Torrance, California

Esophageal occlusion of fetal sheep resulted in a threefold increase in amniotic fluid volume.

1627

Timothy L. Bennett, MD, and James C. Rose, PhD Kansas City, Kansas, and Winston-Salem, North Carolina

Atrial natriuretic factor responses to isotonic volume expansion are similar in pregnant and nonpregnant sheep. Atrial pressure and urine flow changes are unaltered by pregnancy.

Fetal and maternal plasma atrial natriuretic factor responses to angiotensin II infusion

1635

Michael G. Ross, MD, John P. Cardin, MD, Lony Castro, MD, M. Gore Ervin, PhD, and Rosemary D. Leake, MD

Torrance and Los Angeles, California

In spite of similar absolute increases in systemic blood pressure, angiotensin II infusion stimulated increased fetal, although not maternal, plasma atrial natriuretic factor levels.

Angiotensin II vascular smooth-muscle receptors are not down-regulated in near-term pregnant sheep

1641

Hasu R. Mackanjee, MB, ChB, Philip W. Shaul, MD, Ronald R. Magness, PhD, and Charles R. Rosenfeld, MD Dallas, Texas

Although plasma angiotensin II increases threefold to fourfold during ovine pregnancy, receptor density and affinity in vascular smooth muscle from aorta or uterine and mesenteric arteries are unaltered.

Count on FOTA

(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE

INDICATIONS AND USAGE
Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary fract Infections caused by E coli, Klebsiella species (including K pneumoniae), Proteus mirabilis, and Proteus so (which may include the organisms now called Proteus vuigaris, Providencia rettgeri, and Morganella morganii).
Lower Respiratory Tract Infections caused by Streptococcus pneumoniae (formerly D pneumoniae), Staphylococcus aureus (penicillinase- and nonpenicillinase- producing strains), Haemophilus influenzae (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus mirabilis and Serratia marrescens:

Lower Respiratory Tract Infections caused by Streptococcus pneumoniae (formerly D pneumoniae), Staphylococcus aureus (penicillinase-and nonpenicillinase-producing strains), Haemophilus influenzae (including ampicillin-resistant strains), Klebsiella species (including K pneumoniae), E coli, Proteus mirabilis, and Serratia marcescens:

Skin and Skin Structure Infections caused by Staphylococcus aureus (penicillinase-and nonpenicillinase-producing strains), Staphylococcus epidermidis, Streptococcus species (excluding enterococci), E coli, Klebsiella pneumoniae, and Peptococcus: Species (excluding enterococci), E coli, Klebsiella pneumoniae, and Peptococcus species (excluding enterococci), group is streptococcus, Staphylococcus aureus (including penicillinase-and nonpenicillinase-producing strains), Staphylococcus apidermidis, Streptococcus species (excluding enterococci), group is streptococci, E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides species (excluding distasonis, B ovatus, and B thetaiotaomicron), Fusobacterium species, and gram-positive anaerobic cocci (including Peptococcus and Peptosteptococcus species).

Intra-abdominal Infections caused by E coli, Klebsiella species (including K pneumoniae), Streptococcus species (excluding metrococci), Bacteroides species (excluding B distasonis, B ovatus, and B thetaiotaomicron), and Clostridium species.

Bone and Joint Infections caused by Staphylococcus aureus.*

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known, however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has n

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known aliergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures. Pseudomembranous colitics has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may after normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by Clostridium difficile is one primary cause of antibiotic-associated colitis.

Mild cassociated to say respond to drug discontinuance alone. Moderate to severe cases should be

antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by Calificile. Other causes should also bensidered. In common with many other broad-spectrum antibiotics, CEFUTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

PRECAUTIONS
General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachyoardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution. As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of

Seroin and unite creaming seven by safe reaction and produce raise increases in the local of creatining reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of

500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought t developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicul weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatog and spermatocytes; Sertoli and Leydig cells were unaffected, incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 tre animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetra: containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks iniffant dops (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Usage in Pregnancy: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertilit harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response this drug should be used during pregnancy only if clearly needed.

Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

ADVENSE REALFIUNS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80):

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) : nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 2 positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGO (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injectio (1 in 200), and discomment (1 in SGO).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injectio (1 in 300), and discomfort (1 in 500).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hemolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembrar colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION

Treatment: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intra-muscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be de mined by the condition of the patient, severity of the infection, and susceptibility of the causative organ

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN				
Type of infection	Dally Dose	Frequency and Route		
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM		
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM		
Severe	4 grams	2 g every 12 hours IV		
Life-Threatening	6* grams	3 g every 12 hours IV		

*Maximum daily dosage should not exceed 6 grams.

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenousl 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be admistered as soon as the umbilical cord is clamped.

Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION Creatinine Clearance Dose mL/mln Frequen >30 Usual Recommended Dosage Every 12 h 10-30 Usual Recommended Dosage Every 24 h Usual Recommended Dosage Every 48 h <10

*Dose determined by the type and severity of infection, and susceptibility of the causative organism Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/l When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

Males:

Weight (kg) × (140 - age) 72 × serum creatinine (mg/100 mL)

Females:

0.9 x value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

Regulation of corticotropin responsiveness in human fetal adrenal cells 1649 William E. Rainey, PhD, Jan M. McAllister, PhD, E. William Byrd, PhD, J. Ian Mason, PhD, and Bruce R. Carr, MD Dallas, Texas Corticotropin responsiveness in fetal adrenal cells is positively regulated by corticotropin and forskolin. The metabolic clearance rate of epinephrine in the fetus of the diabetic 1655 ewe Jan E. Dickinson, MD, Bruce A. Meyer, MD, Susie Chmielowiec, MS, and Sue M. Palmer, MD Houston, Texas Maturation of the metabolic clearance rate of epinephrine in the fetus of the diabetic ewe is absent, potentially impairing the fetal response to stress. Effects of hyperglycemia on mitochondrial morphology in the region of 1661 the anterior neuropore in the explanted rat embryo model: Evidence for a modified Reid hypothesis as a mechanism for diabetic teratogenesis Brent E. Finley, MD, and Stata Norton, PhD Kansas City, Kansas The effects of hyperglycemia on mitochondrial morphologic characteristics in the explanted rat embryo provide a hypothesis for the mechanism of teratogenesis of maternal diabetes. Longitudinal changes in insulin release and insulin resistance in 1667 nonobese pregnant women Patrick M. Catalano, MD, Elaine D. Tyzbir, MS, Noreen M. Roman, BS, Saeid B. Amini, PhD, and Ethan A.H. Sims, MD Burlington, Vermont, and Cleveland, Ohio Six normal women were found to have a 56% decrease in insulin sensitivity during pregnancy, which was associated with a 3.5-fold increase in insulin response. Streptozocin-induced diabetes mellitus in the pregnant ewe 1673 Jan E. Dickinson, MD, Bruce A. Meyer, MD, Susie Chmielowiec, MS, and Sue M. Palmer, MD Houston, Texas Streptozocin-induced ovine diabetes results in significant maternal hyperglycemia and insulinopenia accompanied by an increase in fetal weight. The changing glycemic response to exercise during pregnancy 1678 James F. Clapp III, MD, and Eleanor L. Capeless, MD Cleveland, Ohio, and Burlington, Vermont During pregnancy there is a progressive reversal of the preconceptional hyperglycemic response to sustained exercise. The changing thermal response to endurance exercise during pregnancy 1684 James F. Clapp III, MD Burlington, Vermont

(Contents continued on page 10A)

The peak rectal temperature attained during running and aerobic dance falls progressively

with advancing gestation.

Maternal levels of prostacyclin, thromboxane, vitamin E, and lipid peroxides throughout normal pregnancy

1690

Yuping Wang, MD, Scott W. Walsh, PhD, Jingde Guo, MD, and Junyan Zhang, MD Richmond, Virginia, and Harbin, People's Republic of China

The maternal concentration ratios of vitamin E to lipid peroxides and prostacyclin to thromboxane progressively favor the antioxidant activity of vitamin E and the vasodilating actions of prostacyclin with advancing gestation in normally pregnant women.

The imbalance between thromboxane and prostacyclin in preeclampsia is associated with an imbalance between lipid peroxides and vitamin E in maternal blood

1695

Yuping Wang, MD, Scott W. Walsh, PhD, Jingde Guo, MD, and Junyan Zhang, MD Richmond, Virginia, and Harbin, People's Republic of China

There is an imbalance of increased lipid peroxides and decreased vitamin E in preeclampsia that correlates with the imbalance of increased thromboxane and decreased prostacyclin.

Antioxidant systems in normal pregnancy and in pregnancy-induced hypertension

1701

Stephen J. Wisdom, MB, ChB, Rhoda Wilson, PhD, James H. McKillop, PhD, and James J. Walker, MB, ChB Glasgow, Scotland

Antioxidant systems in nonpregnant women, pregnant women with normal blood pressure, and women with pregnancy-induced hypertension were compared, with implications for the role of oxidative stress in these conditions.

Selective effects of preeclamptic sera on human endothelial cell procoagulant protein expression

1705

Robert N. Taylor, MD, PhD, David C. Casal, PhD, Lynn A. Jones, MA, Madhu Varma, PhD, James N. Martin, Jr., MD, and James M. Roberts, MD

San Francisco and Sunnyvale, California, and Jackson, Mississippi

Monolayer cultures of human endothelial cells exposed to sera from patients with preeclampsia released more cellular fibronectin than cells treated with sera from matched pregnant controls, but other procoagulant activities were not differentially affected.

Potential role of endothelin-1 in normal and hypertensive pregnancies

1711

Dimitrios S. Mastrogiannis, MD, PhD, William F. O'Brien, MD, Judith Krammer, MD, and Ray Benoit, BS Tampa, Florida

Endothelin-1 concentration is elevated in preeclampsia, laboring patients, and umbilical venous blood.

Endothelin-1-induced vasoconstriction is not mediated by thromboxane release and action in the human fetal-placental circulation

1717

Leslie Myatt, PhD, Gretchen Langdon, BA, Anthony S. Brewer, BS, and Diane E. Brockman, MS Cincinnati, Ohio

Endothelin-1 is a potent vasoconstrictor of the human fetal-placental circulation, but its action is not mediated by thromboxane release or action.

Contents

An endothelial cell model for the investigation of the molecular regulation of fetal vascular tone

1723

Donald J. Dudley, MD, Sharie LaMarche, BS, and Murray D. Mitchell, DPhil Salt Lake City, Utah

Endothelial cell prostacyclin production is regulated by inflammatory cytokines, protein kinase C agonists, and calcium ionophores in a concentration-related fashion.

In utero diagnosis of congenital varicella zoster virus infection by chorionic villus sampling and polymerase chain reaction

1727

Nelson B. Isada, MD, David P. Paar, MD, Mark P. Johnson, MD, Mark I. Evans, MD, Wolfgang Holzgreve, MD, Faisal Qureshi, MD, and Stephen E. Straus, MD

Detroit, Michigan, Münster, Germany, and Bethesda, Maryland

Polymerase chain reaction identified varicella zoster virus-specific genome material in placental tissue by chorionic villus sampling in two patients with chickenpox.

Prenatal diagnosis with fetal cells isolated from maternal blood by multiparameter flow cytometry

1731

James O. Price, PhD, Sherman Elias, MD, Stephen S. Wachtel, PhD, Katherine Klinger, PhD, Michael Dockter, PhD, Avirachan Tharapel, PhD, Lee P. Shulman, MD, Owen P. Phillips, MD, Carole M. Meyers, MD, Donna Shook, MS, and Joe Leigh Simpson, MD

Memphis, Tennessee, and Framingham, Massachusetts

Fetal cells were sorted from maternal blood for prenatal diagnosis of fetal sex, trisomy 21, and trisomy 18.

Absence of hyperinsulinemia in isoimmunized fetuses treated with intravascular transfusion

1737

Michael L. Socol, MD, Sharon L. Dooley, MD, Judith A. Ney, MD, John P. Minogue, DMin, Dietra D. Millard, MD, and Edward S. Ogata, MD

Chicago, Illinois

We were unable to demonstrate hyperinsulinemia in serial blood samples from isoimmunized fetuses treated with intravascular intrauterine transfusion.

Does the brachial artery Doppler flow velocity waveform reflect changes in downstream impedance?

1741

Fiona M. Fairlie, MRCOG, and James J. Walker, MD Glasgow, Scotland

Maternal brachial artery pulsatility index and peak systolic and end-diastolic frequencies were related to changes in downstream impedance, cardiac output, and heart rate in uncomplicated pregnancies.

Effect of pregnancy on the accuracy of light-reflection rheography

1745

John R. Allbert, MD, William E. Roberts, MD, L. Wayne Hess, MD, and John C. Morrison, MD Jackson, Mississippi

The performance of light-reflective rheography used to detect venous thrombosis does not seem to be affected by pregnancy.

(Contents continued on page 12A)

Contents continued from page 11A

Anticardiolipin antibody-positive serum enhances endothelial cell platelet-activating factor production

1748

Richard K. Silver, MD, Luba Adler, MS, Andrew R. Hickman, and Joseph R. Hageman, MD Evanston, Illinois

Anticardiolipin antibodies may promote thrombosis by enhancing the synthesis of platelet-activating factor within vascular endothelial cells.

Combination antibiotics and indomethacin in idiopathic preterm labor: A randomized double-blind clinical trial

1753

Edward R. Newton, MD, Laurence Shields, MD, Louis E. Ridgway III, MD, Michael D. Berkus, MD, and Byron D. Elliott, MD

San Antonio, Texas

The use of ampicillin-sulbactam plus indomethacin did not prevent magnesium sulfate tocolysis failure and subsequent preterm birth.

The progesterone antagonist onapristone increases the effectiveness of oxytocin to produce delivery without changing the myometrial oxytocin receptor concentrations

1760

Krzysztof Chwalisz, MD, PhD, Falk Fahrenholz, PhD, Mario Hackenberg, Robert Garfield, PhD, and Walter Elger, MD, PhD

Berlin and Frankfurt, Germany, and Hamilton, Ontario, Canada

The uterine reactivity to oxytocin was enhanced by onapristone; there was no increase in oxytocin receptors, but a substantial elevation in gap junctions in the myometrium was noted.

Dose-related action of gonadotropin-releasing hormone on basal prostanoid production from the human term placenta

1771

Inn Soo Kang, MD, Mi Kyoung Koong, MD, Julie Forman, BS, and Theresa Marie Siler-Khodr, PhD San Antonio, Texas

Gonadotropin-releasing hormone may have a physiologic role in regulating placental prostanoids by inhibiting their production in a dose-dependent fashion.

Circadian myometrial and endocrine rhythms in the pregnant rhesus macaque: Effects of constant light and timed melatonin infusion

1777

Toshihiko Matsumoto, MD, David L. Hess, PhD, Kanchan M. Kaushal, MS, Guillermo J. Valenzuela, MD, Steven M. Yellon, PhD, and Charles A. Ducsay, PhD Loma Linda, California, and Beaverton, Oregon

Twenty-four-hour patterns in uterine activity and steroid secretion in pregnant rhesus monkeys were maintained in constant light, indicating endogenous circadian rhythms.

Effects of intravenous cocaine on reproductive function in the mated rabbit

1785

Susan J. Atlas, PhD, and Edward E. Wallach, MD Baltimore, Maryland

A single daily intravenous cocaine injection increased ovulation in mated rabbits, although six doses administered immediately after mating delayed preimplantation development but not implantation.

Contents

Expression of extracellular matrix-degrading metalloproteinases by cultured human cytotrophoblast cells: Effects of cell adhesion and immunopurification

1791

Paul Bischof, PhD, Evelyne Friedli, MSc, Marzia Martelli, MSc, and Aldo Campana, MD Geneva, Switzerland

The expression of metalloproteinases by cytotrophoblast cells is described.

Improvement of in vitro fertilization and early embryo development in mice by coculture with human fallopian tube epithelium

1802

Jeffrey M. Goldberg, MD, Essam Al-Dein M. Khalifa, MD, Chad I. Friedman, MD, and Moon H. Kim, MD Columbus, Ohio

Human fallopian tube epithelium explants cocultured with a murine in vitro fertilization model increased fertilization and blastocyst transformation rates over those of conditioned and unconditioned media.

Comparison of intermittent and continuous use of a gonadotropinreleasing hormone antagonist (Nal-Glu) in in vitro fertilization cycles: A preliminary report

1806

Denise L. Cassidenti, MD, Mark V. Sauer, MD, Richard J. Paulson, MD, Edward C. Ditkoff, MD, Jean Rivier, PhD, Samuel S.C. Yen, MD, DSc, and Rogerio A. Lobo, MD Los Angeles, California

The intermittent use of the gonadotropin-releasing hormone antagonist Nal-Glu for in vitro fertilization significantly decreases cycle length and blocks spontaneous luteinizing hormone surges without compromising oocyte and embryo yield when compared with the gonadotropin-releasing hormone agonist.

The gonadotropin-releasing hormone antagonist (Nal-Glu) acutely blocks the luteinizing hormone surge but allows for resumption of folliculogenesis in normal women

1811

Edward C. Ditkoff, MD, Denise L. Cassidenti, MD, Richard J. Paulson, MD, Mark V. Sauer, MD, Wellington L. Paul, PhD, Jean Rivier, PhD, Samuel S.C. Yen, MD, DSc, and Rogerio A. Lobo, MD Los Angeles and Van Nuys, California

Nal-Glu acutely inhibits the luteinizing hormone surge and arrests ovulation but allows follicular rescue with subsequent ovulation and a normal luteal phase.

Reduction of primary posttraumatic adhesion formation with the prostacyclin analog iloprost in a rodent model

1817

Alex Steinleitner, MD, Hovey Lambert, PhD, Mariluz Suarez, BS, Nurys Serpa, BS, and Beverly Robin, BS Miami Beach and Miami, Florida

Perioperative administration of iloprost, a long-lasting prostacyclin analog, inhibited primary adhesion formation in a rodent model.

(Contents continued on page 14A)

Contents continued from page 13A

The effect of the menstrual cycle and of decompression stress on arachidonic acid-induced platelet aggregation and on instrinsic platelet thromboxane production in women compared with men

1821

Sanford M. Markham, MD, Norman H. Dubin, PhD, and John A. Rock, MD Baltimore, Maryland

Platelets from women are more sensitive than platelets from men to arachidonic acid aggregation; this difference is not affected by decompression stress.

Tryptophan and neutral amino acids in premenstrual syndrome

1830

Andrea J. Rapkin, MD, Anthony E. Reading, PhD, Stephanie Woo, BA, and Linda M. Goldman, RNP, MN Los Angeles, California

The ratio of tryptophan to amino acids that compete for transport across the blood-brain barrier was similar in subjects with premenstrual syndrome and controls.

The role of prostaglandins in detrusor instability

1833

Arieh Bergman, MD, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD Los Angeles, California

Women with detrusor instability had significant reductions in the production of 6-keto prostaglandin $F_{1\alpha}$ and no difference in the production of prostaglandin $F_{2\alpha}$ or thromboxane B_2 when compared with women who did not have detrusor instability.

Is 11β -hydroxyandrostenedione a better marker of adrenal androgen excess than dehydroepiandrosterone sulfate?

1837

Frank Z. Stanczyk, PhD, Lilly Chang, MD, Enrico Carmina, MD, Zdnek Putz, CSc, and Rogerio A. Lobo, MD Los Angeles, California, Palermo, Italy, and Lubochna, Czechoslovakia

 11β -hydroxyandrostenedione is a useful marker of adrenal androgen secretion; the greater sensitivity of 11β -hydroxyandrostenedione over dehydroepiandrosterone sulfate to adrenal stimulation and suppression suggests its unique diagnostic use.

Effects of peritoneal macrophages from patients with endometriosis on the proliferation of endometrial carcinoma cell line ECC-1

1842

Ren-jie Zhang, MD, Robert A. Wild, MD, Diane Medders, BS, and Subba Rao Gunupudi, PhD Oklahoma City, Oklahoma, and Sunnyvale, California

Cytokines from peritoneal macrophages in patients with endometriosis may play an important role in the progression of the disease, and such an effect may be mediated by epidermal growth factor or a related growth factor.

Prolonged clearance of intraperitoneal $16\alpha[^{125}I]iodo-17\beta$ -estradiol in presence of ascites

1847

Anton Scharl, MD, Stig Kullander, MD, Matthias W. Beckmann, MD, Jay A. Spicer, MS, Richard J. Baranczuk, PhD, and John A. Holt, PhD

Chicago, Illinois, Malmø, Sweden, and Kansas City and Overland Park, Kansas

Ascites prolongs clearance of intraperitoneal [125I]estradiol from the peritoneal cavity but does not interfere with uptake of radioactivity in estrogen receptor-rich tissues.

Contents

C-jun and jun-B oncogene expression during placental development

1853

Lauren J. Dungy, MD, Tariq A. Siddiqi, MD, and Sohaib Khan, PhD Cincinnati, Ohio

The temporal expression of c-jun and jun-B in human placentas may be related to the proliferation and differentiation of trophoblastic cells.

New monoclonal antibodies identify the glycoprotein carrying the CA 125 epitope

1857

Timothy J. O'Brien, PhD, Lawrence M. Raymond, PhD, Gary A. Bannon, PhD, Danny H. Ford, Hildur Hardardottir, MD, Frank C. Miller, MD, and J. Gerald Quirk, Jr., MD, PhD Little Rock and Fayetteville, Arkansas

New antibodies identify epitopes on the CA 125 glycoprotein similar to and distinct from OC 125.

Specific binding sites for insulin and insulin-like growth factor I in human endometrial cancer

1865

Manubai Nagamani, MD, Charles A. Stuart, MD, Patricia A. Dunhardt, BA, and Mark G. Doherty, MD Galveston, Texas

Specific binding sites for insulin and insulin-like growth factor I are present in human endometrial cancer, and insulin and insulin-like growth factor I may play a role in the growth and development of endometrial cancer.

Increased progesterone concentrations are necessary to suppress interleukin-2-activated human mononuclear cell cytotoxicity

1872

Bruce B. Feinberg, MD, Nenita S. Tan, MD, Bernard Gonik, MD, Peter C. Brath, BS, and Scott W. Walsh, PhD Houston. Texas

The higher placental production of progesterone seen in preeclampsia may be a trophoblast compensatory response to immunoactivated maternal effector cells.

Sister chromatid exchange frequency in directly prepared cytotrophoblasts: Demonstration of in vivo deoxyribonucleic acid damage in pregnant women who smoke cigarettes

1877

Lee P. Shulman, MD, Sherman Elias, MD, Avirachan T. Tharapel, PhD, Lirong Li, PhD, Owen P. Phillips, MD, and Joe Leigh Simpson, MD

Memphis, Tennessee

Cytotrophoblasts from women who smoke cigarettes during pregnancy exhibit increased frequency of sister chromatid exchange, indicating direct placental deoxyribonucleic acid damage.

Cellular localization of müllerian inhibiting substance messenger ribonucleic acid during human ovarian follicular development

1881

Gail F. Whitman, MD, and Cooley G. Pantazis, MD Augusta, Georgia

Localization of reaction product within the cytoplasm demonstrates that active transcription of müllerian inhibiting substance messenger ribonucleic acid occurs within both the fetal and the postnatal human ovary.

Editors' note

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY introduces a new format for abstracts accompanying regular articles, society articles, and Current Investigation articles. Authors submitting these manuscripts to the JOURNAL should provide an abstract of no more than 150 words structured according to the following headings: Objective(s), Study Design, Results, and Conclusion(s). Exceptions to this requirement include Clinical Opinion, Current Development, case report, and brief communication articles. Abstracts for these articles will continue to follow the standard abstract format. Please consult the Information for Authors for details.

The JOURNAL is abstracted and/or indexed in Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague, and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby-Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. She needs PREMARIN to help prevent further bone loss

Calcium¹ and exercise are not enough to prevent postmenopausal osteoporosis, since estrogen deficiency is the primary cause.² PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.³

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.4

PREMARIN® (conjugated actrogens tablets)

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogendependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

For moderate-to-severe vasomotor symptoms and for osteoporosis

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE

PREMARIN® Brand of conjugated estrogens tablets, USP PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquelying base

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal biteding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

2 ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and temale fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares urine. It contains estrone, equilin, and 17 α -dihydroequilin, together with smaller amounts of 17 α -estradiol, equitenin, and 17 α -dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens.

estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and frautresis within

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and karurosis vulvae.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and karurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women for men) with any of the following conditions:

1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients. WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen epiacement doses. Endomentical cancer risk some estrogen dose. In patients on combined estrogen-progestin therapy this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of telal congenital reproductive tract disorders.

Estogen thetapy utiling preglaricy is associated with an incleased risk of rear congeniar reproductive had disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose. Blood pressure should be monitored with estrogen use, especially if high doses are used. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECALTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial mularation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should

include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin

The following drug/laboratory test interactions have occurred to the combinations (oral contraceptives):

1. increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

2. increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T4, levels determined by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaftered.

reflecting the elevated 18G; free 1₂ concentration is unaftered.

3. Impaired glucose tolerance.

4. Reduced response to metyrapone test.

5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See CONTRAINDICATIONS and Royed Warning.

PREGNARCY CATEGORY X: Estrogens should not be used during pregnancy. See CONTRAINDICATIONS and Boxed Warning.

MURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine libromyomata, vaginal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scatp hair, insultism; steepening of corneal curvature, intolerance to contact lenses, headache, migraine, dizziness, mental depression, chorea: increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated strogens tablets, USP

1. Given cyclically for short-term use only. For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic vertificts associated with the menogause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be expelic (eg. three weeks on and one week off). Attempts to discontinue or taper medication should be made at three-to is isk-month intervals.

2. Given cyclically: Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. It bleeding does not occur by the end of this period, the same dosage schedule according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg. th

CONITOL.

Osteoporosis—0 625 mg daily. Administration should be cyclic (eg. three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Altempts to discontinue or taper medication should be made at three- to six-month intervals. Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition. Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Only TRI-NORINYL starts your OC patients with The TRI-NORINYL Total Health Program.™

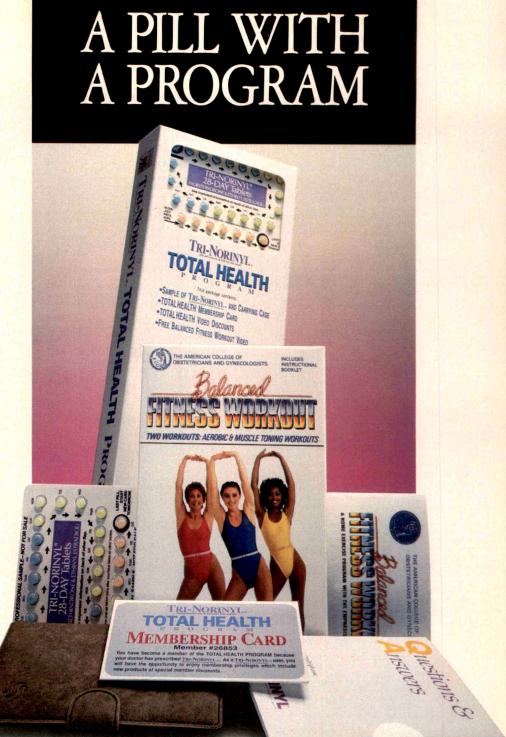

When you start your OC patient with The TRI-NORINYL Total Health Program sample package, you provide the benefits of oral contraception *plus* an exciting new patient-support program.

The TRI-NORINYL Total Health Program sample package contains one cycle of TRI-NORINYL; the attractive Wallette® Pill Dispenser; and a patient Q&A booklet—plus the video and instruction guide, The ACOG Balanced Fitness Workout; and program membership.

The TRI-NORINYL Total Health Program provides a variety of fitness and health information to help women achieve healthier lifestyles.

As part of that goal, Syntex Laboratories is proud to be a sponsor of the American Medical Association's Women's Health Campaign.

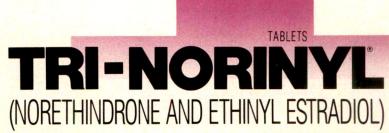

For details about The TRI-NORINYL Total Health Program, please contact your Syntex Representative.

Serious as well as minor side effects have been reported following the use of oral contraceptives. These include thromboembolic disease.

Please see adjacent page for brief summary of prescribing information.

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethnyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

REMONEY 28-DAY Sablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet con-ratins norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Throm bophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders . Cerebral vascular or coronary artery disease . Known or suspected accinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of preg-nancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contra ceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, benatic peoplasia and gallbladder including impoculation and uncontrolled in the processing storage and particularly discussed and particularly discussed in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholes terulemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estro-gen. The effects of long-term use with lower dose formulations of both estrogens and progesto-gens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective of integrated this tables general general magnets account separate are in two types: reconspective or case control studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the ratio of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control. studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not prosatures, but the bods and obtained a descendent relative that are a feet leaf to the descending the individual of the feet leaf to the feet le

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

 Myocardial infarction
 An increased risk of myocardial infarction has been attributed to oral contraceptive use. This An increased risk of importantal infarction has been actituded to did contraceptive base. This first is primarily in smokers or women with other underlying risk factors for coronary artery dis-ease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use ora contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obe-sity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Smil ar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis. 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of throm boembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2 to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discon-tinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke, thypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

in a large study, the relative risk of thombotic strokes has been shown to range from 3 for nor-motensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use raci contraceptives, 7.6 for smokers who used oral contraceptives, 1.6 nor-motensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density [popor etnis (HDL) has been reported with some progestational agents. A decline in serum high den-sity [poporteins has been associated with an increased incidence of ischemic heart disease Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of

therapeutics. For any particular estrogen/progestogen combination, the dosage regimen pre scribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e Persistence of risk of vascular disease

e. Persistence of risk of vascular disease There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40–49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of roal contracep-tives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives, However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

2. ESTIMATES OF MORTHLITT FROM CONTINUED IN TRACE TIVE 20 One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific bene fits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970s—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lover estrogen dose formulations combined with careful restriction of oral contra-ceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which sug-gest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Ferthifty and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular dis asked or televine to plan in 150. The commerce common that shoops of the 150 the commerce cases are asked to the common that the common that the common that the common that the common that the common that the common that the alternative surgical and medical risks associated with pregnancy in older women and with the alternative surgical and medical risks during the common that the alternative surgical and medical risks associated with pregnancy in older women of the alternative surgical and medical risks associated with pregnancy in older that the alternative surgical and medical risks associated with pregnancy in the common that the alternative surgical and medical risks associated with pregnancy in the common that the comm means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE URBANS.

Numerous epidemiological studies have been performed on the incidence of breast, endome trial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the reketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect. neered oranius and uoses. The Cancer and Steriou formome study also Snowed in Diatent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in examination of users and non-users and difference in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there con-tinues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established

4. HEPATIC NEOPLASIA

Renign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 33 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing benatocel Suddies in the United States and Britain have shown an increased risk of developing regulations fulfar carcinoma in long-term (> 8 years) oral confraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver can cers in oral confraceptive users is less than 1 per 1,000,000 users.

5 OCHLAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral con traceptives. Oral contraceptives should be discontinued if there is unexplained partial or com plete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratagenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contracentives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threat ened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnance should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Transcription of the description recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

a. Carbon Turkal Evaluation Train and Evaluation effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and dia betic women should be carefully observed while taking oral contraceptives

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed ear lier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The inci-All indicates in about personner has been reported in mornier manifestor among other women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens. Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contracept tives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure with return to normal after stopping gral contraceptives and there is no difference in the occurrence nsion among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause

11 RIFFRING IRREGILLARITIES

II. DECEVING IRREBULARITIES
Breakthrough bleeding and spotting are sometimes encountered in patients on oral contracep-tives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amen-orrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdo men and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic meas-ures should be conducted for ule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2 LIPIN DISORDERS

2. LITHO DISORDERS Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral confraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregular-ties have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenyloin sodium, and possi-bly with grisedfulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased

norepinephrine-induced platelet aggregability.

b. Increased thryoid binding globulin (186) leading to increased circulating total thryoid hormone, as measured by protein-bound oidine (18b), 1/4 by column or by radioimmunoassay. Free 13 resin uptake is decreased, reflecting the elevated 18G. Free 14 concentration is unaltered.

c. Other binding proteins may be elevated in serum.
d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids, however, free or biologically active levels remain unchanged.
e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum foldte levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

10. PREGNANCY Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections.

Pregnancy Lategory 3. See CUNINAINDICATIONS and WARNINGS Sections.

TI. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weared her child.

INFORMATION FOR THE PATIENT

See PATIENT LABELING. ADVERSE REACTIONS

An increased risk of the following senious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section). Thrombophiebitis - Arterial thromboembolism - Pulmonary embolism - Myocardial infarction - Cerebral hemorrhage - Cerebral thrombosis - Hypertension - Gallibladder disease - Hepatic adenomas, carcinomas or benign liver

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis . Reti nal thromhosis

nal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal carmps and bloading) - Breakthrough bleeding • Sopting • Change in menstrual flow - Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminipton in lection when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Menal Indigensions • Refund for Jerosch or Largeburkrafes • Alexange and Griess • Change in covered to describe the second of the contraction of the second of the contraction of t tal depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in cornea

tal depression • Neduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal
curvature (Stepening) • Intolerance to contact lenses.
The following adverse reactions have been reported in users of oral contraceptives and the
association has been entheir confirmed nor refuted: Pre-menstrual syndrome • Cataracts •
Changes in appetite • Cystitis-like syndrome • Nedadoche • Nervousness • Dizziness • Hirsutsim • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Nemorrhagic eruption •
Vaginits • Porphyra: • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colifis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral con-traceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol. Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the treast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

INFORMATION FOR AUTHORS Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

- 1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.
- 2. Dr. Quilligan—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors. Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval before the experiment is started and approval must be so indicated in the Material and Methods section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must state in the Material and Methods section of the manuscript that the guidelines for the care and use of the animals approved by the local institution were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and Material and Methods section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22×28 cm ($8\frac{1}{2} \times 11$ inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic

degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 key words or short phrases for indexing purposes.

A structured abstract is required for certain types of articles and a standard abstract format is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles, society articles, and Current Investigation articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: Objective(s); Study Design; Results; and Conclusion(s). The Objective(s) reflects the purpose of the study, that is, the hypothesis that is being tested. The Study Design should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The Results include the outcome of the study and statistical significance if appropriate. The Conclusion(s) states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the Journal. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a Journal page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's Manual of Style. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the Results section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles

should conform to abbreviations used in Cumulated Index Medicus.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term figure includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For black-and-white figures, submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For color figures submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted unmounted with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. Color figures are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computergenerated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include standard abstract format, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title.

If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article. The abstract *must* follow the *structured format*.

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include standard abstract format of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of \$60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby-Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms must be completed and sent with each submitted manuscript. If not completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

- —The original and two copies of the manuscript are submitted.
- —The completed checklist is enclosed. The assignment of copyright signed by all authors accompanies the manuscript.
- —Human experimentation has been approved by the local institution as stated in the Material and Methods section.
- —Guidelines for the care and use of nonhuman animals or other species approved by the institution have been followed as indicated in the Material and Methods section.

 The species is named in the title, abstract, key words, and Material and Methods section.
- —The covering letter with essential information is with the manuscript.
- —All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
- —All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
- —Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
- —Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

- —Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
- -Similarities, differences and explanation are provided in

the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

- —These elements are given in the following sequence, and are typed double-spaced.
- -Title.
- —Author(s) name(s) and highest academic degree(s) are shown.
- —City(ies), state(s), and country other than United States in which the study was conducted are given.
- —The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
- -Acknowledgment of financial support is cited.
- —Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
- —If reprints will not be available, this has been stated on the title page.
- —If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
- —At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

- —The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
- —A structured abstract, with 150 words or less, is submitted as required for regular articles, society regular-type articles, and Current Investigation articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
- —A standard abstract is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

- -Are typed double-spaced.
- —Are numbered consecutively in the order they are cited in the text.
- —The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
- —Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

- —Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
- —Three sets of unmounted glossy prints for black-andwhite figures are submitted, properly numbered, labeled, and top indicated on the back of each print.

- Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
- —Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

- -Are provided for each figure.
- —Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

- —Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
- —Tables are cited in numeric sequence in the text.

Triphasil

Levonorgestrel and ethinyl estradiol tablets— Triphasic regimen 21- and 28-day regimens

SINY MUH U BECHUSE SHELL SINKI, MUH THE OCTO

Simple, easy-to-use Day 1 Start

Patient acceptance proven over time

 Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.
 See prescribing information.

See brief summary on adjacent page.

Worldwide Leadership WYETH-AYERS in Female Healthcare W Philadelphia, PA 1910

©1991, Wyeth-Ayerst Laboratories.

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF: TRIPHASIL IN BRIEF:

TRIPHASILE* — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol; 17 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASILE* is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Oral contained captives (COS) as a measure or Contrained property of the following: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Endometrial carcinoma or other known or suspected storpen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding, 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected description. Known or suspected pregnancy.

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contra-ceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke. Use of OCs is associated with increased risks of serious conditions including myocardial infarction, thrombo-

Use of OCs is associated with increased risks of serious conditions including myocardial infarction, thrombomboiling, stroke, hepatic neoplasia, galibladder disease, and hypertension, although risk of serious morbiolity/mortality is very small in healthy women without underlying risk factors. Morbidity/mortality risk increases significantly in other risk factors preservising OCs should be familiar with the following information relating to these risks. (This information is based principally on data involving OCs with higher doses of estrogen and progestogen than those commonly used today. Effect of long-term use of lower estrogen and progestogen formulations is yet to be determined.)

1. Thromboemboilic Disorders and Other Vascular Problems — MYOCARDIAL, INFARCTION (MI). An increased risk of MI has been attributed to OC use. Risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease (i.e. hypertension, hypercholesterolemia, morbid obesity, diabetes). Relative risk of heart attack for current OC users is estimated to be two to six risk is very low under the age of Users. Smoking combined with OC uses on the understance substantially is incidence of Mis in women in their mid-thirties or older with smoking accounting for majority of excess cases. Mortality rates associated with circulatory disease increase substantially in smokers over the age of 40 among OC users. OCs may compound effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. OCs have been shown to increase blood pressure among users (see Warnings). Similar effects or wisk factors are associated with increased risk of heart disease. Use OCs with caution in women with cardiovascular disease risk factors.

THROMBOEMBOLISM. Increased risk of thromboembolic and thrombotic disease associated with OC use is well established. In cas

due to OCs is not related to length of use and disappears after pill use is stopped.

A 2- to 4-fold increase in relative risk of postoperative thromboembolic complications has been reported with OCs. Relative risk of venous thrombosis in women with predisposing conditions is twice that of women without such conditions. If feasible, discontinue OCs at least 4 weeks prior to and for 2 weeks after elective surgery of a type associated with increased risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is associated with an increased thromboembolic risk, start OCs no earlier than 4 to 6 weeks after delivery in women not breast-feeding, or a mid-trimester pregnancy termination. CEREBROVASCULAR DISEASES. OCs increase relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes); in general, risk is greatest among older (> 35 years), hypertensive women who smoke. Hypertension is a risk factor for users and nonusers, for both types of strokes, while smoking interests in circases hemorrhagic stroke is.

who smoke. Hyperfension is a risk factor for users and nonusers, for both types of strokes, while smoking interacts to increase hemorrhagic stroke risks. ROSE-RELATED RISK OF VASCILLAR DISEASE FROM OCS. A positive association has been observed between amount of estrogen and progestogen in OCs and vascular disease risk. A decline in serum high density lipoproteins (HDL) is reported with many progestational agents. Serum HDL decline is associated with increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, net effect depends on balance achieved between doese of estrogen and progestogen and nature and absolute amount of progestogen used. Consider amount of both hormones in the choice of an OC.

The dosage regimen prescribed should contain the least amount of estrogen and progestogen compatible with a low failure rate and individual patient needs. Start new acceptors on preparations containing less than 50 mcg of

estrogen.

PERSISTENCE OF RISK OF VASCULAR DISEASE. Two studies have shown persistence of vascular disease risk for ever-users of OCs. In a U.S. study. MI risk after OC discontinuation persists for at least 9 years in women 40-49 years who had used OCs for five or more years; increased risk was not demonstrated in other age groups. In a study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after OCs stopped, although excess risk was very small. Both studies used OC formulations with 50 micrograms or higher of estropers.

scoped, almosping access risk was very similar both studies development of estrogens.

2. Estimates of Mortality from Contraceptive Use — A study using data from several sources concluded that with the exception of OC users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The possibility of increased mortality risk with age for OC users is based on data from the 1970s — but reported in 1983. However, current practice involves use of lower estrogen dose formulations combined with careful restriction of OC use to women without the various risk factors listed in this labeling.

Changes in practice and new data suggesting that cardiovascular disease risk with OCs may be less than previously observed prompted the Fertility and Maternal Health Drugs Advisory Committee to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with OC use after age 40 in healthy nonsmokers (even with newer low-dose formulations) greater potential health risks are associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if effective, acceptable contraception is not available.

The Committee concluded that the benefits of OC use by healthy nonsmoking women over 40 may outweigh the possible risks. Older women, as all women who take OCs, should use the lowest possible effective dose formulation.

3. Carcinoma of the Reproductive Organs — Numerous epidemiological studies have looked at the incidence of

formulation.

3. Carcimona of the Reproductive Organs — Numerous epidemiological studies have looked at the incidence of breast, endometrial, ovarian and centical cancer in women using OCs. Overwhelming evidence suggests that CC use is not associated with an increase in risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer, risk for at least a decade following long-term use. A few studies show a slightly increased relative risk of developing breast cancer, although the methodology of these studies, including differences in examination of users and nonusers, and in age at start of use, has been questioned.

Some studies suggest that CC use is associated with an increased risk of cervical intraepithelial neoplasia in some populations of women. However, controversy continues about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between OC use and breast and cervical cancers, a cause and effect relationship has not been established.

4. Hepatic Neoplasia — Benign hepatic adenomas are associated with OC use, although incidence is rare in the U.S. Indirect calculations estimate attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

British studies have shown an increased risk of hepatocellular carcinoma in long-term (> 8 years) OC users; these cancers are extremely rare in the U.S. and attributable risk (excess incidence) of liver cancers in OC users approaches less than one per million users.

5. Ocular Lesions — There are clinical case reports of retinal thrombosis with OC use. Discontinue OCs if there is unexplained partial or complete loss of vision, onset of proptosis or diplopia, papilledema, or retinal vascular lesions; undertake appropriate diagnostic and therapeutic measures immediately.

lesions; undertake appropriate diagnostic and therapeutic measures immediately, 6. Oral-Contracepture Use Betine or During Farty Prognancy.— Extensive epidemiological studies revealed no increased risk of birth defects when OCs used prior to pregnancy Studies do not suggest a teratogenic effect, particularly insodar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. OC-induced withdrawal bleeding should not be used as a pregnancy test. Do not use OCs during pregnancy to treat threatened or habitual abortion. Rule out pregnancy if two consecutive periods missed before continuing OC use. If oatlent has not adhered to prescribed schedule, consider pregnancy at time of first missed period. Discontinue OC if pregnancy confirmed.

7. Galibladder Disease—Earlier studies reported an increased lifetime relative risk of galibladder surgery in users of OCs and estrogens; more recent studies show that the relative risk of developing galibladder disease among OC users may be minimal, which may be related to use of formulations with lower hormonal estrogen and propestogen doses.

8. Carbohydrate and Lipid Metabolic Effects — OCs cause glucose intolerance in a significant percentage of users OCs with greater than 75 µg of estropen cause hyperinsulinism; lower estropen doses cause less glucose intolerance. Progestopens increase insulin secretion and create insulin resistance (effect varies with different agents). Observe prediabetic and diabetic women carefully while taking OCs. In non-diabetic women, OCs have no apparent effect on fasting blood glucose.

no application effect on inasting sound spicoses.

A small proportion of women will have persistent hypertriglyceridemia while on OCs. Changes in serum triglycerides and lipoprotein levels have been reported in OC users (see Warnings).

9. Elevated Blood Pressure—Increase in blood pressure has been reported in women on OCs, increase is more likely in older OC users and with continued use. Data show that incidence of hypertension increases with

likely in older OC users and with continued use. Data show that incidence of hypertension increases with increasing quantities of progestogen of progestogen and increasing quantities of progestogen of hypertension or hypertension-related diseases, or renal disease to use another contraceptive method. Monitor hypertensive women electing to use OCs closely, discontinue OC if significant blood pressure elevation occurs For most women, elevated blood pressure returns to normal after OC stopped. No difference in occurrence of hypertension among ever- and never-users exists.

10. Headache — Discontinue OC and evaluate cause at onset or exacerbation of higraine, or if new pattern of headache (i.e. recurrent, persistent, severe) develops.

11. Bleeding irregularities — Breakthrough bleeding and spotting sometimes occur, especially during first 3 months of use. Type and dose of progestogen may be important. Consider non-hormonal causes and take adequate diagnostic measures to rule out malignancy or pregnancy in event of breakthrough bleeding, as with any abnormal vaginal bleeding. If pathology excluded, time or a formulation change may solve the problem. In the event of amenorrhea, rule out pregnancy. Some women encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

event of amenormae, rule out pregnancy. Some women encounter post-pin amenormea or oligomenormea, especially when such a condition was pre-existent.

Procautions

1. Physical Examination and Follow Up — A complete medical history and physical examination should be taken prior to initiation or reinstitution of OCs and at least annually during use. Physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent ahommal vaginal bleeding, conduct appropriate diagnostic measures to rule out malignancy. Monitor women with strong tamily history of breast cancer or who have breast nodules with particular care. 2. Lipid Disorders — Follow women being treated for hyperlipidemias closely if they elect to use OCs. Some progestogens may elevate LDL levels and may render control of hyperlipidemias more difficult. (See Warnings): 3. Liver Function — Discontinue OC if jaundice develops Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. Fluid Retention — OCs may cause some degree of fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions possibly aggravated by fluid retention. 5. Emotional Disorders — If significant depression occurs stop medication and use alternate contraceptive method in attempts to determine if symptom is drug related. Observe carefully those with history of degression and stop drug if depression recurs to serious degree. 6. Contact

Lenses — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities are associated with concomitant rifampin use A similar association, though less marked, is suggested with barbiturates, henryblutazone, phenytoin sodium, and possibly with prisorlytivin. and menstrual irregularities are associated with concomitant rifampin use. A similar association, though less marked, is suggested with barbiturates, phenylbufazone, phenylon sodium, and possibly with griseofulvin, ampicillin and tetracyclines. B. Interactors with Laboratory Tests—Certain endocrine—and liver-function tests and blood components may be affected by OCs: a. Increased prothrombin and factors VII. VIII. IX, and X, decreased antithrombin 3: increased norepinephrine-induced platelet aggregability b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI). 14 by column or by radioimmunoassay Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. C. Other binding proteins may be elevated in serum d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids. Tree or biologically active levels remain unchanged. e. friglycerides may be increased f. Glucose tolerance may be decreased g. Serum folate levels may be depreased by OCs. This may be of clinical significance if woman becomes pregnant shortly after stopping OC. 9. Carcinogenesis — See Warnings section. 10. Pregnancy — Pregnancy Category X. See Contraindications and Warnings. 11. Nursing Mothers — Small amounts of OC steroids have been identified in milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, OCs given in postpartum period may interfere with lactation by decreasing breast milk cunnity and quality If possible, advise nursing mother to use other forms of contraception, not OCs. until child is completely wearsed. completely weaped

compilerly wearned.

Information for the Patient — See Patient Package Labelling.

Adverse Reactions — An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis: arterial thromboembolism; pulmonary embolism; myocardial infarction cerebral hemorrhage; cerebral thrombosis; hypertension; galloladder disease; nepatic adenomas or benign liver turnors

cerebral hemorrhagic cerebral thrombosis; hypertension; gallbladder disease; hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and OC use, although additional confirmatory studies are needed: mesenteric thrombosis; retinal thrombosis. The following adverse reactions have been reported in patients on OCs and are believed to be drug-related; nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorhea; temporary intertility; after treatment discontinued; edema; melasma which may persist; breast changes; tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical etosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash lallergid; mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in OC users and the association is neither confirmed nor refuted; congenital anomalies; premenstrual syndrome; cataracts; ontic neuritis; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsuitism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria; impaired renal function, hemolytic uremic syndrome; Budd-Chiari syndrome; acne; changes in iibidd; colinis; sickle-cell disease; cerebral-vascular disease with mitral valve prolages; lupus-like syndromes.

Deverdosage—Serious iil effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health** Benefits — The following noncontraceptive health benefits related to OC use are supported by epidemiological studies that largely utilized OC formulations containing doses exceeding 0.035

decreased incidence of ovarian cancer.

Dosage and Administration — For maximum contraceptive effectiveness, take TRIPHASIL* (levonorgestrel and ethinyl estraciol tablets — triphasic regimen 21- and 28-day regimens) exactly as directed and at intervals not over 24 hours.

(If TRIPHASIL* is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.) For full details on dosage and administration see prescribing information in package insert.

CONSULTANTS

Consultants for the American Journal of Obstetrics and Gynecology

September 1, 1990—August 31, 1991

The Editors and Mosby-Year Book, Inc., take this opportunity to acknowledge those reviewers who have contributed many hours and much effort in the evaluation of manuscripts submitted to the JOURNAL during the past year. Without their interest and help, publication of the JOURNAL would be very difficult indeed. We also continue to seek advice from reviewers and readers alike as regards their overall evaluation of the JOURNAL.

Abdella, Thomas N., Phoenix, Arizona Abell, Ernest L., Buffalo, New York Abplanalp, Judith, Galveston, Texas Abraham, Guy E., Torrance, California Abramowicz, Jacques S., Rochester, New York Abrams, Barbara, Berkeley, California Abrams, Richard, Denver, Colorado Abrams, Robert M., Gainesville, Florida Abrams, Walter, Gainesville, Florida Acker, David B., Boston, Massachusetts Acosta, Anibal, Norfolk, Virginia Adamsons, Karlis, San Juan, Puerto Rico Adashi, Eli Y., Baltimore, Maryland Addison, W.
